Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of the information in a particular situation remains the professional responsibility of the practitioner.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in the publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in their clinical practice.

To purchase additional copies of this book, call our customer service department at (800) 638-3030 or fax orders to (301) 223-2320. International customers should call (301) 223-2300.

Visit Lippincott Williams & Wilkins on the Internet: at LWW.com. Lippincott Williams & Wilkins customer service representatives are available from 8:30 am to 6 pm, EST.

TO OUR PATIENTS

*who inspire us to continually strive to improve their health,  
function, and quality of life*

TO OUR TEACHERS

*who encouraged us to develop a scientific approach to medicine  
and instilled in us the need for continuous learning*

TO OUR STUDENTS

*who challenge and stimulate us to stay at the cutting edge;  
they are our hope for the future*

TO OUR COLLEAGUES,

*who have gone before us, who are with us  
and who will follow us*

TO OUR FAMILIES

*who provided the support and patience necessary*

## PART I

### Principles of Assessment and Evaluation

<b>1</b>	<b>Clinical Evaluation</b>	<b>3</b>
	Ibrahim A. Aksoy, John A. Freeman, Kirsten S. Paynter, Bryan K. Ganter, Rolland P. Erickson, Matthew A. Butters, and Stephen F. Noll	
<b>2</b>	<b>The Physical Examination</b>	<b>55</b>
	Joseph H. Feinberg and Peter J. Moley	
<b>3</b>	<b>Assessment of Human Muscle Function</b>	<b>69</b>
	Walter R. Frontera and Jan Lexell	
<b>4</b>	<b>Electrodiagnostic Evaluation of the Peripheral Nervous System</b>	<b>89</b>
	Lawrence R. Robinson	
<b>5</b>	<b>Human Walking</b>	<b>121</b>
	William S. Pease and Brian L. Bowyer	
<b>6</b>	<b>Imaging Techniques Relative to Rehabilitation</b>	<b>139</b>
	Edgar Colón, Eduardo Labat, Gory Ballester, Jorge Vidal, and Angel Gomez	
<b>7</b>	<b>Diagnostic Ultrasound</b>	<b>211</b>
	Henry L. Lew, Tyng-Guey Wang, Wen-Chung Tsai, and Yi-Pin Chiang	
<b>8</b>	<b>Principles and Applications of Measurement Methods</b>	<b>221</b>
	Steven R. Hinderer and Kathleen A. Hinderer	
<b>9</b>	<b>Functional Evaluation and Management of Self-care and Other Activities of Daily Living</b>	<b>243</b>
	Charles H. Christiansen, Sandra L. Rogers, and Kristine L. Haertl	
<b>10</b>	<b>Disability Determination</b>	<b>289</b>
	Robert D. Rondinelli and Richard T. Katz	
<b>11</b>	<b>Applying the ICF in Rehabilitation Medicine</b>	<b>301</b>
	Gerold Stucki, Nenad Kostanjsek, Bedirhan Üstün, Thomas Ewert, and Alarcos Cieza	

<b>12</b>	<b>Systematically Assessing and Improving the Quality and Outcomes of Medical Rehabilitation Programs</b>	<b>325</b>
-----------	---	------------

Mark V. Johnston, Kenneth J. Ottenbacher, James E. Graham, Patricia A. Findley, and Anne C. Hansen

## PART II

### The Rehabilitation Team: Systems-Based Practice

<b>13</b>	<b>Rehabilitation Team Function and Prescriptions, Referrals, and Order Writing</b>	<b>359</b>
	John C. King, Karen J. Blankenship, William Schalla, and Amit Mehta	
<b>14</b>	<b>Psychological Aspects of Rehabilitation</b>	<b>387</b>
	Daniel E. Rohe	
<b>15</b>	<b>Speech, Language, Swallowing, and Auditory Rehabilitation</b>	<b>413</b>
	Beth Solomon, Carmen Brewer, Martin B. Brodsky, Jeffrey B. Palmer, and Jennifer Ryder	
<b>16</b>	<b>Sexuality and Disability</b>	<b>445</b>
	Stacy Elliot and Andrei Krassioukov	
<b>17</b>	<b>Vocational Rehabilitation, Independent Living, and Consumerism</b>	<b>459</b>
	Debra Homa and David DeLambo	
<b>18</b>	<b>Community Participation and the Environment: Theoretical, Assessment and Clinical Implications</b>	<b>473</b>
	Julie J. Keysor and Daniel K. White	
<b>19</b>	<b>Systems-Based Practice of Physical Medicine and Rehabilitation</b>	<b>485</b>
	Bruce M. Gans, Carolyn C. Zollar, Martha Kendrick, and Jared Fleisher	
<b>20</b>	<b>Ethical Issues in Rehabilitation Medicine</b>	<b>501</b>
	Janet F. Haas	
<b>21</b>	<b>Interactions with the Medicolegal System</b>	<b>515</b>
	Steve R. Geiringer	

## 22 International Aspects of the Practice of Rehabilitation Medicine 525

Haim Ring, Alessandro Giustini, Hugo Núñez Bernadet, Leonard S.W. Li, Mark Young, Nicolas Christodoulou, and Chang-il Park

### PART III

## Major Conditions 549

### 23 Stroke Rehabilitation 551

Joel Stein and Murray E. Brandstater

### 24 Traumatic Brain Injury 575

John Whyte, Jennie Ponsford, Thomas Watanabe, and Tessa Hart

### 25 Multiple Sclerosis 625

Francis Bethoux and Alexander Rae-Grant

### 26 Rehabilitation of Persons with Parkinson's Disease and Other Movement Disorders 645

Ron Hirschberg, Nutan Sharma, and Donna Moxley Scarborough

### 27 Rehabilitation of Spinal Cord Injury 665

Steven Kirshblum and Monifa Brooks

### 28 Adult Motor Neuron Disease 717

Lisa S. Krivickas and Gregory T. Carter

### 29 Peripheral Neuropathy 741

Mark A. Thomas and Maya Therattil

### 30 Myopathy 757

Jay J. Han and David D. Kilmer

### 31 Osteoarthritis 781

Todd P. Stitik, Jong-Hyun Kim, Doreen Stiskal, Patrick Foye, Robert Nadler, James Wyss, and Sausheen Heslop

### 32 Disorders of the Cervical Spine 811

Jason S. Lipetz and David I. Lipetz

### 33 Rehabilitation of Lumbar Spine Disorders: An Evidence-Based Clinical Practice Approach 837

Stefano Negrini, Fabio Zaina, Michele Romano, Salvatore Atanasio, Claudia Fusco, and Carlo Trevisan

### 34 Scoliosis and Other Spinal Deformities 883

Scott M. Paul

### 35 Upper Extremity Soft-Tissue Injuries 907

Mark D. Klaiman and Kathleen Fink

### 36 Cumulative Trauma Disorders 923

Philip Chiou and Joanne Borg-Stein

### 37 Hand Disorders 937

Keith A. Bengtson, Jeffrey S. Brault, and Lynn H. Gerber

### 38 Foot Disorders 953

Eric L. Kolodin, Thomas Vitale, and Lynn H. Gerber

### 39 The Prevention and Treatment of Osteoporosis 979

Patricia Graham, Robert A. Adler, Francis J. Bonner, and Gopi Kasturi

### 40 Rehabilitation of the Patient with Rheumatic Diseases 1015

Galen O. Joe, Jeanne E. Hicks, and Lynn H. Gerber

### 41 Cardiac Rehabilitation 1075

Matthew Bartels

### 42 Rehabilitation of the Patient with Respiratory Dysfunction 1099

John R. Bach and Eric Altschuler

### 43 Burn Rehabilitation 1125

Jeffrey C. Schneider and M. Catherine Spires

### 44 Rehabilitation for Patients with Cancer Diagnoses 1151

Mary M. Vargo, Justin C. Riutta, and Deborah J. Franklin

### 45 Vascular Diseases 1179

Karen L. Andrews, Gustavo S. Oderich, Haraldur Bjarnason, Gail L. Gamble, David M. Strick, and Vincent J. Yacyshyn

### 46 Transplantation Medicine: A Rehabilitation Perspective 1207

Ross D. Zafonte and Michael Munin

### 47 Rehabilitation of the Individual with HIV 1227

Stephen F. Levinson and Steven M. Fine

### PART IV

## Secondary Conditions and Complications 1247

### 48 Physical Inactivity: Physiological and Functional Impairments and Their Treatment 1249

Eugen M. Halar and Kathleen R. Bell

### 49 Treatment of the Patient with Chronic Pain 1273

Nicolas E. Walsh, Daniel Santa Maria, and Maxim Eckmann

### 50 Spasticity and Muscle Overactivity as Components of the Upper Motor Neuron Syndrome 1319

Elie P. Elovic, Michal E. Eisenberg, and Neil N. Jasey, Jr

<b>51</b>	Neurogenic Bladder and Bowel	1345
	Todd A. Linsenmeyer, James M. Stone, and Steven A. Steins	

<b>52</b>	Pressure Ulcers	1393
	Chester H. Ho and Kath Bogie	

## PART V

### Special Populations 1411

<b>53</b>	Sports Medicine	1413
	Gerard A. Malanga, Jose A. Ramirez-Del Toro, Jay E. Bowen, Joseph H. Feinberg, and Garrett S. Hyman	

<b>54</b>	Physical Activity for People with Disabilities	1437
	James H. Rimmer and Jennifer A. Gray-Stanley	

<b>55</b>	Performing Arts Medicine	1459
	Sonya Rissmiller and Katie Weatherhogg	

<b>56</b>	Children with Disabilities	1475
	Martin Diamond and Michael Armento	

<b>57</b>	Adults with Childhood-Onset Disabling Conditions	1503
	Joyce Oleszek, Laura Pickler, and Dennis Matthews	

<b>58</b>	Empowering Women with Disabilities to be Self-Determining in their Health Care	1517
	Kristi L. Kirschner, Judy Panko Reis, Debjani Mukherjee, and Cassing Hammond	

<b>59</b>	Aging and Rehabilitation	1545
	Gary S. Clark, Patrick Kortebein, and Hilary C. Siebens	

<b>60</b>	Primary Care for Persons with Disability	1587
	William L. Bockenek, Gerben DeJong, Indira S. Lanig, Michael Friedland, and Amanda Harrington	

## PART VI

### Management Methods 1617

<b>61</b>	Therapeutic Exercise	1619
	Martin D. Hoffman, William J. Kraemer, and Daniel A. Judelson	

<b>62</b>	Aquatic Rehabilitation	1673
	Bruce E. Becker and Andrew J. Cole	

<b>63</b>	Therapeutic Physical Agents	1691
	Jeffrey R. Basford and G. David Baxter	

<b>64</b>	Manipulation, Massage, and Traction	1713
	J. Michael Wieting, Michael T. Andary, Todd G. Holmes, Adam Cugalj, Neal Cross, and Gregory Thompson	

<b>65</b>	Pharmacotherapy of Disability	1743
	Todd P. Stitik, Robert Klecz, Brian D. Greenwald, and Jiaxin J. Tran	

<b>66</b>	The Pharmacology of Analgesic Agents	1805
	David J. Jones and Antonio Hernandez	

<b>67</b>	Injection Procedures	1815
	Nicolas E. Walsh and Maxim Eckmann	

<b>68</b>	Spinal Injection Procedures	1875
	Boqing Chen, Todd P. Stitik, Patrick M. Foye, Jong-Hyun Kim, Michael Mehnert, Christopher Castro, Steve Aydin, Glen Cheng, and Evish Kamrava	

<b>69</b>	Palliative Care Symptom Management	1905
	Andrea L. Cheville	

<b>70</b>	Evolution of Biofeedback in Physical Medicine and Rehabilitation	1937
	Steve L. Wolf and He (Helen) Huang	

<b>71</b>	Therapeutic Electrical Stimulation in Neurorehabilitation	1953
	Lynne R. Sheffler, Jayme S. Knutson, and John Chae	

<b>72</b>	Functional Neuromuscular Electrical Stimulation	1977
	Jayme S. Knutson, Lynne R. Sheffler, and John Chae	

<b>73</b>	Assistive Technology	1997
	Cathy Bodine	

<b>74</b>	Upper and Lower Extremity Prosthetics	2017
	Nicolas E. Walsh, Gordon Bosker, and Daniel Santa Maria	

<b>75</b>	Upper Limb Orthotics	2051
	Heikki Uustal	

<b>76</b>	Lower Extremity Orthotics, Shoes, and Gait Aids	2063
	Alberto Esquenazi	

<b>77</b>	Spinal Orthotics	2081
	Ferne Pomerantz and Eva Durand	

<b>78</b>	Wheelchairs	2097
	Michael L. Boninger, Laura McClure, Rory A. Cooper, Mark Schmeler, and Rosemarie Cooper	

<b>79</b>	Complementary and Alternative Medicine	2119
	Ann C. Cotter, Lisa Bartoli, Jay Rosenfeld, Robert Schulman, and David Jung Seto

# CONTRIBUTORS

**Robert A. Adler, MD**

Richmond, Virginia

**Ibrahim A. Aksoy, MD, PhD**

Department of Physical Medicine and Rehabilitation  
Mayo Clinic College of Medicine  
Rochester, Minnesota

**Eric Altschuler, MD**

Department of Physical Medicine and Rehabilitation  
University of Medicine and Dentistry of New Jersey  
New Jersey Medical School  
Newark, New Jersey

**Fabrisia Ambrosio, PhD, MPT**

Assistant Professor  
Department of Physical Medicine and Rehabilitation  
University of Pittsburgh  
Pittsburgh, Pennsylvania

**Michael T. Andary, MD, MS**

Professor  
Department of Physical Medicine and Rehabilitation  
Michigan State University College of Osteopathic Medicine  
East Lansing, Minnesota

**Karen L. Andrews, MD**

Assistant Professor  
Department of Physical Medicine and Rehabilitation  
Mayo Clinic College of Medicine  
Rochester, Minnesota

**Michael Armento, MD**

Clinical Assistant Professor  
Department of Physical Medicine and Rehabilitation  
University of Medicine and Dentistry of New Jersey  
New Jersey Medical School  
Newark, New Jersey  
Children's Specialized Hospital  
Mountainside, New Jersey

**Anthony Atala, MD**

Director  
Institute for Regenerative Medicine  
Wake Forest University Baptist Medical Center  
Winston-Salem, North Carolina

**Salvatore Atanasio, MD**

Vigevano, Italy

**Steve Aydin, MD**

Department of Physical Medicine and Rehabilitation  
University of Medicine and Dentistry of New Jersey  
New Jersey Medical School  
Newark, New Jersey

**John R. Bach, MD**

Professor and Vice Chairman  
Associate Medical Director  
Department of Physical Medicine and Rehabilitation  
University of Medicine and Dentistry of New Jersey  
New Jersey Medical School  
Newark, New Jersey

**Gory Ballester, MD**

Assistant Professor  
Department of Radiological Sciences  
University of Puerto Rico School of Medicine  
San Juan, Puerto Rico

**Matthew Bartels, MD**

Associate Professor  
Department of Rehabilitation and Regenerative  
Medicine  
Columbia University College of Physicians and Surgeons  
New York, New York

**Lisa Bartoli, DO**

Private Practice  
New York, New York

**Jeffrey R. Basford, MD, PhD**

Professor and Consultant  
Physical Medicine and Rehabilitation  
Mayo Clinic College of Medicine  
Rochester, Minnesota

**G. David Baxter, MD**

Savannah, Georgia

**Bruce E. Becker, MD**

Clinical Professor  
Department of Rehabilitation Medicine  
University of Washington  
Seattle, Washington  
St. Luke's Rehabilitation Institute  
Spokane, Washington

**Kathleen R. Bell, MD**

Associate Professor  
Department of Rehabilitation Medicine  
University of Washington  
Seattle, Washington

**Keith A. Bengtson, MD**

Assistant Professor  
Department of Physical Medicine and Rehabilitation  
Director of Hand Rehabilitation  
Mayo Clinic College of Medicine  
Rochester, Minnesota

**Hugo Núñez Bernadet, MD**

Punta Del Este, Uruguay

**Francois Bethoux, MD**

Director, Rehabilitation Services  
Mellen Center for MS Treatment and Research  
The Cleveland Clinic Foundation  
Cleveland, Ohio

**Haraldur Bjarnason, MD**

Professor  
Department of Radiology  
Mayo Clinic College of Medicine  
Chief, Vascular and Interventional Radiology  
Department of Radiology  
Mayo Clinic  
Rochester, Minnesota

**Karen J. Blankenship, MA, RN**

Director of Clinical Operations (Retired)  
Department of Physical Medicine and Rehabilitation  
University Hospital  
San Antonio, Texas

**William L. Bockenek, MD**

Chairman  
Department of Physical Medicine and Rehabilitation  
Carolinas Medical Center  
Medical Director  
Carolinas Rehabilitation  
Charlotte, North Carolina

**Cathy Bodine, PhD**

Assistant Professor  
Department of Rehabilitation Medicine  
University of Colorado School of Medicine  
Denver, Colorado

**Kath Bogie, DPhil**

Cleveland, Ohio

**Michael L. Boninger, MD**

Chair and Associate Dean for Medical Student Research  
Department of Physical Medicine and Rehabilitation  
University of Pittsburgh School of Medicine  
Medical Director  
Human Engineering Research Laboratories  
VA Pittsburgh Healthcare System  
Pittsburgh, Pennsylvania

**Francis Bonner, Jr., MD**

Clinical Professor of Medicine  
Drexel University College of Medicine  
Philadelphia, Pennsylvania  
Medical Director  
Rehabilitation Center at South Jersey  
Vineland, New Jersey

**Joanne Borg-Stein, MD**

Assistant Professor  
Department of Physical Medicine and Rehabilitation  
Boston, Massachusetts  
Medical Director  
Spaulding Rehabilitation Hospital–Wellesley and Newton Wellesley Hospital  
Newton, Massachusetts

**Gordon Bosker, MEd, CPO**

Instructor/Research

Mayo Clinic  
Rochester, Minnesota

**Yi-Pin Chiang, MD**

Mackay Memorial Hospital  
Taipei, Taiwan, ROC

**Martin K. Childers, DO, PhD**

Professor  
Department of Neurology and Wake Forest Institute for Regenerative Medicine  
Wake Forest University Health Sciences  
Winston-Salem, North Carolina

**Philip Chiou, MD**

Resident Physician  
Department of Physical Medicine and Rehabilitation  
Harvard Medical School  
Resident Physician  
Department of Physical Medicine and Rehabilitation  
Spaulding Rehabilitation Hospital  
Boston, Massachusetts

**George Christ, PhD**

Wake Forest Institute for Regenerative Medicine  
Wake Forest University Health Sciences  
Winston-Salem, North Carolina

**Charles H. Christiansen, EdD, OTR OT(C), FAOTA**

Clinical Professor  
Division of Rehabilitation Sciences  
University of Texas Medical Branch  
Galveston, Texas

**Nicolas Christodoulou, MD**

Nicosia, Cyprus

**Alarcos Cieza, MPH**

Munich, Germany

**Gary S. Clark, MD, MMM, CPE**

Professor and Chair  
Department of Physical Medicine and Rehabilitation  
Case Western Reserve University  
Medical Director  
MetroHealth Rehabilitation Institute of Ohio  
MetroHealth Medical Center  
Cleveland, Ohio

**Andrew J. Cole, MD**

Clinical Associate Professor  
Department of Rehabilitation Medicine  
University of Washington  
Seattle, Washington

**Edgar Colón, MD**

Professor  
Chief, Diagnostic Radiology  
Department of Radiological Sciences  
University of Puerto Rico School of Medicine  
San Juan, Puerto Rico

**Rory A. Cooper, PhD**

Distinguished Professor and FISA/PVA Endowed Chair  
Department of Rehabilitation Science and Technology  
Senior Career Scientist and Director  
Human Engineering Research Laboratories  
VA Pittsburgh Healthcare System  
Pittsburgh, Pennsylvania

**Rosemarie Cooper, MPT, ATP**

Clinical Instructor  
Department of Rehabilitation Science and Technology  
University of Pittsburgh  
Pittsburgh, Pennsylvania

**Ann Nancy Cotter, MD**

Associate Clinical Professor  
Department of Physical Medicine and Rehabilitation  
University of Medicine and Dentistry of New Jersey  
New Jersey Medical School  
Newark, New Jersey  
Medical Director  
Integrative Medicine Division  
Atlantic Health  
Morristown and Summit, New Jersey

**Steven C. Cramer, MD**

Professor  
Department of Neurology, Anatomy and Neurobiology  
University of California, Irvine  
Irvine, California

**Neal A. Cross, PhD**

Chair and Professor  
Department of Anatomy  
Lincoln Memorial University – DeBusk College of Orthopaedic Medicine  
Harrogate, Tennessee

**Adam Cugalj, DO**

Clinical Instructor  
Department of Physical Medicine and Rehabilitation  
Michigan State University College of Osteopathic Medicine  
East Lansing, Michigan  
Private Practice  
Granite Physiatry, PLLC  
Concord, New Hampshire

**Martin Diamond, MD**

Children's Specialized Hospital  
Mountainside, New Jersey

**David A. DeLambo, RhD, CRC**

Associate Professor  
Department of Rehabilitation Counseling  
University of Wisconsin-Stout  
Menomonie, Wisconsin

**Gerben DeJong, PhD**

Professor  
Department of Physical Medicine and Rehabilitation  
Georgetown University  
Senior Fellow and Director  
Center for Post-acute Studies  
National Rehabilitation Hospital  
Washington, DC

**Eva Durand, MD**

Private Practice  
Valley Stream, New York

**Maxim Eckmann, MD**

San Antonio, Texas

**Michael E. Eisenberg, MD**

New York, New York

**Stacy L. Elliott, MD**

Clinical Professor  
Department of Psychiatry and Urological Sciences  
University of British Columbia  
Medical Director  
British Columbia Centre for Sexual Medicine  
Department of Psychiatry  
Vancouver Coastal Health Authority  
Vancouver, British Columbia, Canada

**Elie P. Elovic, MD**

Professor  
Department of Physical Medicine and Rehabilitation  
University of Utah School of Medicine  
Chief  
Department of Physical Medicine and Rehabilitation  
University of Utah Health Center  
Salt Lake City, Utah

**Rolland P. Erickson, MD**

Assistant Professor  
Department of Physical Medicine and Rehabilitation  
Mayo Clinic College of Medicine  
Rochester, Minnesota  
Consultant  
Department of Physical Medicine and Rehabilitation  
Mayo Clinic Arizona  
Scottsdale, Arizona

**Alberto Esquenazi, MD**

Professor  
Department of Physical Medicine and Rehabilitation  
Thomas Jefferson University  
Philadelphia, Pennsylvania  
Chair and Professor  
Department of Physical Medicine and Rehabilitation  
Moss Rehabilitation Hospital  
Elkins Park, Pennsylvania

**Thomas Ewert, PhD**

Munich, Germany

**Joseph H. Feinberg, MD, MS**

Associate Professor  
Department of Psychiatry  
Cornell University  
Vice Chairman  
Department of Psychiatry  
Hospital for Special Surgery  
New York, New York

Assistant Professor  
School of Social Work  
Rutgers University  
New Brunswick, New Jersey

**Steven M. Fine, MD, PhD**

Assistant Professor of Medicine  
Infectious Diseases Division  
University of Rochester Medical Center  
Infectious Disease Attending  
Department of Internal Medicine  
Highland Hospital  
Rochester, New York

**Kathleen Fink, MD**

Clinical Associate Professor  
Department of Physical Medicine and Rehabilitation  
Georgetown University Hospital  
Washington, DC  
National Rehabilitation Hospital  
Bethesda, Maryland

**Jared Fleisher, JD**

Attorney  
Patton Boggs LLP  
Washington, DC

**Patrick Foye, MD**

Department of Physical Medicine and Rehabilitation  
University of Medicine and Dentistry of New Jersey  
New Jersey Medical School  
Newark, New Jersey

**Deborah J. Franklin, PhD, MD**

Director  
Cancer Rehabilitation  
Department of Rehabilitation Medicine  
Thomas Jefferson University Hospital  
Philadelphia, Pennsylvania

**John A. Freeman, DO**

Instructor  
Department of Physical Medicine and Rehabilitation  
Mayo Clinic College of Medicine  
Rochester, Minnesota  
Consultant  
Department of Physical Medicine and Rehabilitation  
Mayo Clinic Arizona  
Scottsdale, Arizona

**Michael B. Friedland, MD**

Associate Clinical Professor  
Department of Medicine  
University of North Carolina at Chapel Hill  
Chapel Hill, North Carolina  
Staff Physician  
Department of Internal Medicine  
Charlotte Medical Clinic  
Carolinas Medical Center  
Charlotte, North Carolina

**Mark Furth, PhD**

Technical Development Officer  
Wake Forest Institute for Regenerative Medicine  
Wake Forest University School of Medicine  
Winston-Salem, North Carolina

**Claudio Fusco, MD**

Milan, Italy

**Gail L. Gamble, MD**

Medical Director of Cancer Rehabilitation  
Department of Physical Medicine and Rehabilitation  
Rehabilitation Institute of Chicago  
Chicago, Illinois

**Bryan K. Ganter, MD**

Assistant Professor  
Department of Physical Medicine and Rehabilitation  
Mayo Clinic College of Medicine  
Rochester, Minnesota  
Consultant  
Department of Physical Medicine and Rehabilitation  
Mayo Clinic Scottsdale  
Scottsdale, Arizona

**Steve R. Geiringer, MD**

Clinical Professor  
Department of Physical Medicine and Rehabilitation  
Wayne State University  
Detroit, Michigan

**Lynn H. Gerber, MD**

Director  
Center for the Study of Chronic Illness and Disability  
University Professor  
George Mason University  
Fairfax, Virginia

**Alessandro Giustini, MD**

Arezzo, Italy

**Angel Gomez, MD**

Assistant Professor  
Department of Radiological Sciences  
University of Puerto Rico School of Medicine  
San Juan, Puerto Rico

**James E. Graham, PhD, DC**

Assistant Professor  
Division of Rehabilitation Services  
University of Texas Medical Branch  
Galveston, Texas

**Patricia Graham, MD**

Princeton, New Jersey

**Jennifer A. Gray-Stanley, PhD, MPP**

Assistant Professor  
Department of Public Health and Health Education  
School of Nursing and Health Studies  
Northern Illinois University  
DeKalb, Illinois

**Brian D. Greenwald, MD**

Assistant Professor  
Department of Rehabilitation Medicine  
Mt. Sinai School of Medicine  
New York, New York

**Janet F. Haas, MD**

William Penn Foundation  
Philadelphia, Pennsylvania

**Kristine L. Haertl, PhD, ORT/L**

Associate Professor  
Department of Occupational Science and Occupational Therapy  
St. Catherine University  
St. Paul, Minnesota

**Eugene M. Halar, MD**

Professor Emeritus  
Department of Rehabilitation Medicine  
University of Washington School of Medicine  
Seattle, Washington

**Cassing Hammond, MD**

Assistant Professor  
Obstetrics and Gynecology  
Northwestern University  
Director  
Department of Obstetrics and Gynecology  
Northwestern Memorial Hospital  
Chicago, Illinois

**Jay J. Han, MD**

Director  
Neuromuscular Medicine Fellowship  
Department of Physical Medicine and Rehabilitation  
University of California Davis Medical Center  
Sacramento, California

**Anne C. Hansen, MS/CCC-SP**

Stroke and Neurovascular Program Coordinator  
Froedtert and the Medical College of Wisconsin  
Milwaukee, Wisconsin

**Amanda Harrington, MD**

SCIM Fellow  
Department of Physical Medicine and Rehabilitation  
Case Western Reserve University  
MetroHealth Rehabilitation Institute of Ohio  
Cleveland, Ohio

**Tessa Hart, PhD**

Institute Scientist  
Moss Rehabilitation Research Institute  
MossRehab  
Elkins Park, Pennsylvania

**Antonio Hernandez, MD**

Associate Professor  
Department of Anesthesiology  
University of Texas Health Science Center at San Antonio  
Director of Cardiothoracic and Transplant Anesthesiology  
Department of Anesthesiology  
University Hospital  
San Antonio, Texas

**Sausheen Heslop, MD**

New York Hospital  
Queens, New York

**Stefan Hesse, MD**

Professor  
Department of Neurological Rehabilitation  
Charité-University Medicine Berlin  
Chief Consultant  
Department of Neurology  
Medical Park Berlin  
Berlin, Germany

**Jeanne E. Hicks, MD, FACP**

Former Adjunct Associate Professor of Rehabilitation Medicine  
Department of Orthopaedic Surgery  
Georgetown University Medical Center  
Washington, DC  
Former Deputy Chief  
Department of Rehabilitation Medicine  
Warren G. Magnuson Clinical Center  
National Institutes of Health  
Bethesda, Maryland

**Kathleen A. Hinderer, PhD, MPT, PT**

Ann Arbor, Michigan

**Stephen R. Hinderer, MD, MS, PT**

Associate Professor  
Department of Physical Medicine and Rehabilitation  
Wayne State University School of Medicine  
Rehabilitation Institute of Michigan  
Detroit, Michigan

**Ron Hirschberg, MD**

Instructor  
Department of Physical Medicine and Rehabilitation  
Harvard Medical School  
Spaulding Rehabilitation Hospital  
Boston, Massachusetts

**Chester Ho, MD**

Assistant Professor  
Department of Physical Medicine & Rehabilitation  
Case Western Reserve University  
Chief, Spinal Cord Injury Service  
Louis Stokes Department of Veterans Affairs Medical Center  
Cleveland, Ohio

**Martin D. Hoffman, MD**

Professor of Clinical Physical Medicine and Rehabilitation  
University of California—Davis School of Medicine  
Sacramento, California  
Chief, Physical Medicine and Rehabilitation Service  
VA Northern California Health Care System  
Mather, California

**Neville Hogan, PhD**

Professor  
Department of Mechanical Engineering  
Massachusetts Institute of Technology  
Newman Laboratory for Biomechanics and Human Rehabilitation  
Veterans Health Administration  
Department of Rehabilitation and Development  
Cambridge, Massachusetts

**Debra Homa, PhD, CVE, CRC**

Associate Professor  
Department of Rehabilitation and Counseling  
University of Wisconsin-Stout  
Menomonie, Wisconsin

**He (Helen) Huang, PhD**

Assistant Professor  
Director of Neuromuscular Rehabilitation Engineering Laboratory  
Department of Electrical, Computer, and Biomedical Engineering  
University of Rhode Island  
Kingston, Rhode Island

**Garrett S. Hyman, MD**

Northwest Spine and Sports Physicians  
Bellevue, Washington

**Neil N. Jasey, Jr.**

New York, New York

**Alan M. Jette, PhD**

Director  
Health and Disability Research Institute  
Boston University School of Public Health  
Boston, Massachusetts

**Galen O. Joe, MD**

Deputy Chief  
Department of Rehabilitation  
National Institutes of Health  
Bethesda, Maryland

**Mark V. Johnston, PhD**

Professor  
Department of Occupational Therapy  
College of Health Sciences  
University of Wisconsin-Milwaukee  
Milwaukee, Wisconsin

**David J. Jones, PhD**

Professor  
Departments of Anesthesiology and Pharmacology  
University of Texas Health Science Center at San Antonio  
San Antonio, Texas

**Daniel A. Judelson, MD**

Storrs, Connecticut

**Evish Kamrava, MD**

Department of Physical Medicine and Rehabilitation  
University of Medicine and Dentistry of New Jersey  
New Jersey Medical School  
Newark, New Jersey

**Gopi Kasturi, MD**

Royal Oak, Michigan

**Richard T. Katz, MD**

St. Louis, Missouri

**Martha Kendrick, JD**

Partner  
Patton Boggs LLP  
Washington, DC

**Julie J. Keysor, PhD, PT**

Associate Professor  
Department of Physical Therapy and Athletic Training  
Boston University School of Medicine  
Boston, Massachusetts

**David D. Kilmer, MD (deceased)**

Professor and Chair  
Department of Physical Medicine and Rehabilitation  
University of California Davis School of Medicine  
Davis, California

**Jong-Hyun Kim, MD**

Department of Physical Medicine and Rehabilitation  
University of Medicine and Dentistry of New Jersey  
New Jersey Medical School  
Newark, New Jersey

**John C. King, MD**

Professor  
Department of Rehabilitation Medicine  
The University of Texas Health Science Center at San Antonio  
Director  
Reeves Rehabilitation Center  
University Hospital  
San Antonio, Texas

**Steven Kirshblum, MD**

Associate Professor  
Department of Physical Medicine and Rehabilitation  
University of Medicine and Dentistry of New Jersey  
New Jersey Medical School  
Newark, New Jersey  
Associate Medical Director and Director of Spinal Cord Injury  
Services  
Kessler Institute for Rehabilitation  
West Orange, New Jersey

**Kristi L. Kirschner, MD**

Professor  
Clinical Medical Humanities and Bioethics and PM&R  
Northwestern University  
Feinberg School of Medicine  
Attending Physician  
Schwab Rehabilitation Hospital  
Chicago, Illinois

**Mark D. Klaiman, MD**

Consultant  
Department of Rehabilitation Medicine  
National Institutes of Health  
Active Associate  
Department of Rehabilitation  
Suburban Hospital  
Bethesda, Maryland

**Robert Klecz, MD**

Clinical Chief of Orthopedic Rehabilitation  
Kessler Institute for Rehabilitation, Saddle Brook  
Campus  
Saddle Brook, New Jersey

**Jayme Knutson, PhD**

Researcher  
Department of Biomedical Engineering  
Case Western Reserve University  
Bioscientific Staff  
Department of Physical Medicine and Rehabilitation  
MetroHealth Medical Center  
Cleveland, Ohio

**Eric L. Kolodin, DPM**

Assistant Attending  
Department of Surgery, Section of Podiatry  
Saint Barnabas Medical Center  
Livingston, New Jersey

**Patrick Kortebein, MD**

Assistant Professor  
Physical Medicine & Rehabilitation, and Geriatrics  
University of Arkansas for Medical Sciences  
Little Rock, Arkansas

**Nenad Kostanjsek, MD**

Geneva, Switzerland

**William J. Kraemer, PhD**

Professor of Kinesiology, Physiology, and Neurobiology  
The University of Connecticut School of Medicine  
Storrs, Connecticut

**Andrei Krassioukov, MD, PhD, FRCPC**

Associate Professor  
Division of Physical Medicine and Rehabilitation  
Associate Director and Scientist, ICORD  
Director of Autonomic Research Unit  
Staff Physician  
Spinal Cord Program  
GF Strong Rehabilitation Centre  
Department of Medicine  
University of British Columbia  
Vancouver, British Columbia, Canada

**Hermano Igo Krebs, PhD**

Principal Research Scientist and Lecturer  
Massachusetts Institute of Technology  
Department of Mechanical Engineering  
Cambridge, Massachusetts

**Lisa S. Krivickas, MD (deceased)**

Associate Professor  
Harvard Medical School  
Associate Chief  
Physical Medicine and Rehabilitation  
Director of EMG  
Spaulding Rehabilitation Hospital  
Boston, Massachusetts

**Eduardo J. Labat, MD**

Neuroradiology Fellow  
Department of Radiology  
Mallinckrodt Institute of Radiology  
Washington University  
St. Louis, Missouri

**Indira S. Lanig, MD**

Department of Physical Medicine and Rehabilitation  
University of Colorado Denver School of Medicine  
Denver, Colorado

**Stephen F. Levinson, MD, PhD**

Associate Professor  
Department of Physical Medicine and Rehabilitation  
Wayne State University  
Detroit, Michigan  
Physiatrist  
Kessler Institute for Rehabilitation  
West Orange, New Jersey

**Henry L. Lew, MD, PhD**

Professor, Department of Physical Medicine and Rehabilitation  
Virginia Commonwealth University, School of Medicine  
National Consultant for Research and Education  
Defense and Veterans Brain Injury Center (DVBIC)  
Richmond, Virginia

**Jan Lexell, MD, PhD**

Professor  
Division of Rehabilitation Medicine  
Department of Clinical Sciences, Lund  
Lund University  
Medical Director  
Department of Rehabilitation Medicine  
Skåne University Hospital  
Lund, Sweden

**Leonard S.W. Li, MD**

Hong Kong, China

**Todd A. Linsenmeyer, MD**

Associate Professor  
Department of Physical Medicine and Rehabilitation  
Department of Surgery (Division of Urology)  
University of Medicine and Dentistry of New Jersey  
New Jersey Medical School  
Newark, New Jersey  
Director of Urology  
Kessler Institute for Rehabilitation  
West Orange, New Jersey

**David Lipetz, MSPT, OCS, Cert. MDT**

Private Practice  
Garden City, New York

**Jason S. Lipetz, MD**

Assistant Professor  
Department of Rehabilitation Medicine  
Albert Einstein College of Medicine  
Bronx, New York  
Attending Physician  
Department of Physical Medicine and Rehabilitation  
North Shore Long Island Jewish Hospital  
Manhasset/Glencove/New Hyde Park, New York

**Albert C. Lo, MD, PhD**

Assistant Professor  
Departments of Neurology, Community Health, Engineering  
Brown University  
Staff Physician  
Department of Internal Medicine  
Providence Veterans Affairs Medical Center  
Providence, Rhode Island

**Gerard A. Malanga, MD**

Associate Professor  
Department of Physical Medicine and Rehabilitation  
University of Medicine and Dentistry of New Jersey  
New Jersey Medical School  
Newark, New Jersey  
Director, Sports, Spine, and Orthopedic  
Rehabilitation  
Kessler Institute for Rehabilitation  
West Orange, New Jersey

**Chad Markert, PhD**

Postdoctoral Research Fellow  
Wake Forest Institute for Regenerative Medicine  
Wake Forest University  
Winston-Salem, North Carolina

Washington, DC

# P R E F A C E

**T**he field of *Physical Medicine and Rehabilitation* focuses on the restoration of health and function and reintegration of the patient into the community. The goal of *Physical Medicine and Rehabilitation: Principles and Practice* is to organize, summarize, discuss, and make available knowledge in the field to assist the developing or established practitioner in these endeavors. This fifth edition is divided in two volumes for ease of use by the practitioner and to accommodate the dramatic increase in information and knowledge in the field of physical medicine and rehabilitation since the publication of the fourth edition. This edition also introduces a classification of the chapters in new sections.

The content of the book has been extensively revised and expanded. There are six new chapters and over thirty major revisions in this edition. Our goal is to provide a comprehensive, thorough, and multidisciplinary discussion covering the depth and breadth of the science of physical medicine and rehabilitation and the evidence that supports current best practice. Chapters cover the scientific fundamentals of our field as well as the state-of-the-art clinical interventions used in the treatment and rehabilitation of patients with a wide variety of diseases and disabilities. Authors for each chapter were chosen for their experience and expertise in their given topic. This text reflects the efforts of over two hundred contributing authors representing all parts of the world.

The editorial board for this edition has changed. Joel A. DeLisa, MD, Editor-in-Chief of the first four editions of the book has become Editor Emeritus. Walter R. Frontera, MD, PhD has assumed the role of Editor-in-Chief. In addition, a wonderful group of three Editors and nine Associate Editors have worked diligently to make this fifth edition a world class treatise.

The editors of this edition would like to express their appreciation to each of the editors and authors of previous editions. Their work has contributed in a special way to this current version. We also would like to acknowledge the hard work of the authors of this current edition; they have helped create an excellent source of knowledge for those interested in physical medicine and rehabilitation. Their commitment and dedication have made this an exciting and productive effort.

We hope this fifth edition of *Physical Medicine and Rehabilitation: Principles and Practice* contributes significantly to the advancement of the field. As an essential resource for the training and continuing education of medical rehabilitation professionals, this text will help ensure that the care they provide to people with disabling conditions is of the highest quality, resulting in improvement in their health, function, and quality of life.

PART

I

# **Principles of Assessment and Evaluation**

# Clinical Evaluation

## OVERVIEW

Physical medicine and rehabilitation focuses on the restoration of function and the subsequent reintegration of the patient into the community. As with other branches of medicine, the cornerstone of physical medicine and rehabilitation is a meticulous and thorough clinical evaluation of the patient. Therapeutic intervention by physiatrists must be based on proper assessment of the patient. Impaired function cannot be isolated from preexisting and concurrent medical problems or from the social circumstances of the individual patient.

## Evaluation of Function

Medical diagnosis focuses on the historical clues and physical findings that lead the examiner to the correct identification of disease. After a medical diagnosis is established, the physiatrist must ascertain functional consequences of the disease. Appropriate clinical evaluation requires the examiner to have a clear understanding of the distinctions among the disease, body functions, activity limitations, and participation restrictions, as discussed in Chapter 19.

If a disease cannot be eliminated or its severity cannot be reduced through medical or surgical means, measures are used to minimize its impact on functioning. For example, a weak muscle can be strengthened or a hearing impairment can be minimized with the use of an electronic aid. When disease process that leads to impaired functioning cannot be eliminated or its severity cannot be reduced, physiatric intervention must address the limitations on activity and the restrictions on participation. For successful rehabilitation, the physiatrist not only must address the consequences of impaired functioning directly but also must identify intact functional capabilities. When intact capabilities and their use are augmented and adapted to new uses, functional independence can be enhanced.

## Case 1

AW had gained much enjoyment and self-esteem as a competitive runner before a spinal cord injury that left him with paraplegia. During and after inpatient rehabilitation, he vigorously pursued a cardiovascular and upper extremity conditioning program. He obtained an ultralightweight sport wheelchair and resumed competitive athletics as a wheelchair racer, winning several regional races.

*Comment:* AW's intact capabilities included normal arm strength, a competitive spirit, and self-discipline. Through augmentation and adaptation and with the use of an appropriate

wheelchair, he regained enjoyment and self-esteem in his athletic endeavors.

Sometimes it is not possible to ascertain the specific disease responsible for a patient's constellation of historical, physical, and laboratory findings. Medical management must then address the symptoms of the patient. Although diagnosis is highly desirable, it is not a prerequisite to the identification and subsequent management of functional loss. To determine the expectations of future activity in relation to past activity, the physiatrist should attempt to characterize the temporal nature of the disease process over time.

## Case 2

FZ, a 62-year-old woman, had difficulty climbing stairs. When questioned, she revealed that she and her husband had been in the habit of taking a 30-minute evening walk for many years. However, 2 years earlier, fatigue began to limit her walk to no more than a few blocks. During the previous year, she had had difficulty rising from low seating, and 6 months previously, she reluctantly quit taking walks. During the preceding few weeks, she had found that climbing stairs was a burden, and she had started taking showers because she needed assistance getting out of the bathtub.

FZ reported no sensory deficits. Physical examination showed hypotonic muscle stretch reflexes and predominantly proximal muscle weakness. Electrodiagnostic studies and muscle biopsy demonstrated a noninflammatory myopathy; however, further extensive evaluation failed to determine a cause. FZ was provided with a bath bench, a toilet seat riser, a lightweight folding wheelchair for long-distance mobility, and a cane for short distances. She was instructed in safe ambulation with the cane, operation of the wheelchair, energy conservation techniques, and the proper placement of bathroom safety bars. Safe automobile operation was documented, and she was provided with documentation to obtain a handicapped parking permit. The functional impact of potentially progressive muscle weakness was discussed with her, and she was given supportive counseling.

When FZ returned for a follow-up examination 1 month later, muscle testing showed only a slight progression of her weakness, and her functional capabilities were unchanged. Another follow-up examination was scheduled for 6 weeks later.

*Comment:* Although a specific diagnosis was not established, rehabilitation intervention addressed the patient's specific functional losses. Serial evaluations at regular follow-up intervals allowed the physiatrist to identify and minimize future functional loss.

### Comprehensiveness of Evaluation

The scope of physical medicine and rehabilitation encompasses more than a single organ system. Attention to the whole person is paramount. The objective of the physiatrist is to eliminate disability and restore functioning. The goal is to empower the individual to attain the fullest possible physical, mental, social, and economic independence by maximizing activity and participation. Consequently, the evaluation must assess not only the disease but also the way the disease affects and is affected by the person's family and social environment, vocational responsibilities and economic state, avocational interests, hopes, and dreams.

### Cases 3 and 4

CC, a 63-year-old piano tuner, had a left cerebral infarction manifested only as minimal dysfunction of the dominant right hand. Despite demonstrating discrete function of the digits of the involved hand on physical examination, he was psychologically devastated to find that he could no longer accomplish the fine and precise motor patterns necessary to continue in his profession.

BD, a 63-year-old corporate attorney, had a left cerebral infarction resulting in severe spastic weakness of his nondominant upper extremity. He completed some paperwork every day during his inpatient rehabilitation and returned to full-time employment shortly after finishing treatment.

*Comment:* For each person, the degree of functional impairment is uniquely and disproportionately related to the extent of resultant limitations in activity and restrictions in participation.

### Interdisciplinary Nature of Evaluation

Although most of this chapter addresses the patient history and physical examination as related to the rehabilitation evaluation, these are only part of the comprehensive rehabilitation assessment. This statement is not meant to deprecate the usefulness

of these traditional tools for the physician. Both are of critical importance and serve as the basis for further evaluation; yet, by their very nature, they are also limited. Speech and language disorders can inhibit communication. Subjective interpretation of the facts by the patient and the family can cloud the objective assessment of function. Performance cannot be optimally assessed by interview and physical examination alone.

For example, asking the patient about ambulation skills during the interview may identify a potential problem, but such skills can only be assessed objectively and reliably by having the physician and physical therapist observe the patient's ambulation in various situations. Likewise, the occupational therapist must assess the performance of activities of daily living, and the rehabilitation nurse must assess the safety and judgment of the hospitalized patient. The speech therapist furnishes a measured assessment of language function and, through special communication skills, may obtain information from the patient that was missed during the interview. The rehabilitation psychologist provides a quantified and standardized assessment of cognitive and perceptual function and a skilled assessment of the patient's current psychological state. Through interaction with the patient's family and employer, the social worker can provide useful information that is otherwise unavailable regarding the patient's social support system and economic resources. The concept of the physical medicine and rehabilitation team applies not only to evaluation of the patient but also to ongoing management of the rehabilitation process in the outpatient as well as the inpatient practice setting.

### SETTING AND PURPOSE

Because of the expanding scope of physical medicine and rehabilitation, the evaluation setting can be diverse.

**TABLE 1.1     The Physical Medicine and Rehabilitation Evaluation: Setting and Purpose**

Setting	Purpose
Hospital	
Inpatient rehabilitation unit	Comprehensive evaluation by the rehabilitation team
Off-service consultation	Assessment by physiatrist of potential for rehabilitation benefit
Clinic	
General physiatry clinic	Comprehensive evaluation by the team
	Assessment by physiatrist of potential for rehabilitation benefit
	Thorough evaluation of musculoskeletal or spine disorder
Special clinic	Thorough evaluation of specific disease group (e.g., muscular dystrophy or sports injury)
Day rehabilitation program	Comprehensive evaluation by rehabilitation team
Impairment or disability clinic	Evaluation determined by requirement of referring agency (e.g., workers' compensation or Social Security Administration)
Community nursing home	Comprehensive evaluation by rehabilitation team
	Limited assessment by selected members of rehabilitation team
	Assessment by physiatrist of potential for rehabilitation benefit
School	Limited evaluation of functioning
	Limited evaluation for participation in sports
Transitional living facilities	Comprehensive evaluation by rehabilitation team
	Limited assessment of specific problem

A necessary corollary to the setting is the purpose of the evaluation. Both the setting and the purpose will affect the format and extent of the evaluation. Traditionally, the inpatient rehabilitation unit or the outpatient psychiatry clinic has been the optimal setting for a comprehensive evaluation by the entire rehabilitation team. However, in these days of increasing medical costs and intervention by the government and other third-party payers, creative approaches may be required to accomplish comprehensive rehabilitation evaluations in the clinic and elsewhere in the community (Table 1-1).

## PATIENT HISTORY

Ordinarily, the patient history is obtained in an interview of the patient by the psychiatrist. If communication disorders and cognitive deficits are encountered during the evaluation, additional corroborative information must be obtained from significant others accompanying the patient. The spouse and family members can be valuable resources. The psychiatrist may also find it necessary to interview other caregivers, such as paid attendants, public health nurses, and home health agency aides.

The major components of the patient history are the chief report of symptoms, the history of the present illness, the functional history, the past medical history, a review of systems, the patient profile, and the family history.

### Chief Report of Symptoms

The goal in assessing the chief report of symptoms is to document the patient's primary concern in his or her own words. Patients often report an impairment in the form of a symptom that may suggest a certain disease or group of diseases. A report of "chest pain when I walk up a flight of stairs" suggests cardiac disease, whereas a report that "my hands ache and go numb when I drive" hints at carpal tunnel syndrome.

Of equal importance is the recognition that a chief report of impaired function may also be the first implication of activity limitation or participation restriction. A homemaker's report that "my balance has been getting worse and I've fallen several times" may be related to disease involving the vestibular system and to disability created by unsafe ambulation. Similarly, a farmer's declaration that "I can no longer climb up onto my tractor" not only suggests a neuromuscular or orthopedic disease but also conveys that the disorder has resulted in disability because the patient is not able to fulfill vocational expectations.

### History of Present Illness

The history of the present illness is obtained when the patient relates the development of the present illness. When necessary, patients should be asked to define the specific words they use. Specific questions relating to a particular symptom can also help focus the interview. Using these techniques, the physician

**TABLE 1.2** Analysis of Symptoms

1. Date of onset
2. Character and severity
3. Location and extension
4. Time relationships
5. Associated symptoms
6. Aggravating and alleviating factors
7. Previous treatment and effects
8. Progress, noting remission and exacerbations

From Mayo Clinic Department of Neurology. *Mayo Clinic Examinations in Neurology*. 7th ed. St. Louis: Mosby; 1998. Used with permission of Mayo Foundation for Medical Education and Research.

can gently guide the patient to follow a chronological sequence and to fully describe the symptoms and their consequences. Above all, the patient should be allowed to tell the story. More than one symptom may be elicited during the interview, and the physician should document each problem in an orderly fashion (Table 1-2) (1).

A complete list of the patient's current medications should be obtained. Polypharmacy is commonly encountered in people with chronic disease, at times with striking adverse effects. Side effects of medications can further impede cognition, psychological state, vascular reflexes, balance, bowel and bladder control, muscle tone, and coordination already impaired by the present illness or injury.

The history of the present illness should include a record of handedness, which is important in many areas of rehabilitation.

### Functional History

The psychiatric evaluation of a patient with chronic disease often reveals impaired function. The functional history enables the psychiatrist to characterize the disabilities that have resulted from disease and to identify remaining functional capabilities. Some physicians consider the functional history to be part of the history of the present illness, whereas others view it as a separate segment of the patient interview. The examiner must know not only the functional status associated with the present illness but also the premorbid level of function.

Although the specific organization of the activities of daily living varies somewhat, the following elements of personal independence are constant: communication, eating, grooming, bathing, toileting, dressing, bed activities, transfers, and mobility.

When obtaining the functional history, the physician may record in a descriptive paragraph the patient's level of independence in each activity. However, functional stability is best communicated, followed over time, and made accessible for study when the physician uses a standard functional assessment scale, as discussed in Chapter 28.

## Communication

Because a major component of physical medicine and rehabilitation practice is patient education, effective communication is essential. The interviewer must assess the patient's communication options. In the clinical situation, this aspect of the evaluation blurs the distinction between history and physical examination. It is difficult to interact with the patient in a meaningful way without coincidentally examining his or her ability to communicate; significant speech and language deficiencies become obvious. However, for purposes of discussion, certain facets of the assessment relate more specifically to the history and will be discussed here. Additional facets are presented below in the section on the physical examination.

Speech and language pathology has provided clinicians with numerous classification systems for speech and language disorders (see Chapter 15). From a functional view, the elements of communication hinge on four abilities related to speech and language (2):

1. Listening
2. Reading
3. Speaking
4. Writing

By assessing these factors as well as comprehension and memory, the examiner can determine a patient's communication abilities. Representative questions include the following:

1. Do you have difficulty hearing?
2. Do you use a hearing aid?
3. Do you have difficulty reading?
4. Do you need glasses to read?
5. Do others find it hard to understand what you say?
6. Do you have problems putting your thoughts into words?
7. Do you have difficulty finding words?
8. Can you write?
9. Can you type?
10. Do you use any communication aids?

## Eating

The abilities to present solid food and liquids to the mouth, to chew, and to swallow are basic skills taken for granted by able-bodied people. However, in patients with neurologic, orthopedic, or oncologic disorders, these tasks can be formidable. Dysfunctional eating is associated with far-reaching consequences, such as malnutrition, aspiration pneumonitis, and depression. As in the assessment of other skills for activities of daily living, eating function should be assessed specifically and methodically.

Representative questions include the following:

1. Can you eat without help?
2. Do you have difficulty opening containers or pouring liquids?
3. Can you cut meat?
4. Do you have difficulty handling a fork, knife, or spoon?

5. Do you have problems bringing food or beverages to your mouth?
6. Do you have problems chewing?
7. Do you have difficulty swallowing solids or liquids?
8. Do you ever choke?
9. Do you regurgitate food or liquids through your nose?

Patients with nasogastric or gastrostomy tubes should be asked who helps them prepare and administer their feedings. The type, quantity, and schedule of feedings should be recorded.

## Grooming

Grooming may not be considered as important as feeding. However, impaired functioning that leads to deficits in grooming can have deleterious effects on hygiene as well as on body image and self-esteem. Consequently, grooming skills should be of real concern to the rehabilitation team.

Representative questions include the following:

1. Can you brush your teeth without help?
2. Can you remove and replace your dentures without help?
3. Do you have problems fixing or combing your hair?
4. Can you apply your makeup independently?
5. Do you have problems shaving?
6. Can you apply deodorant without assistance?

## Bathing

The ability to maintain cleanliness also has far-reaching physical and psychosocial implications. Deficits in cleaning can result in skin maceration and ulceration, skin and systemic infections, and the spread of disease to others. Patients should be questioned about their ability to bath independently.

Representative questions include the following:

1. Can you take a tub bath or shower without assistance?
2. Do you feel safe in the tub or shower?
3. Do you use a bath bench or shower chair?
4. Can you accomplish a sponge bath without help?
5. Are there parts of your body that you cannot reach?

For patients with sensory deficits, bathing is also a convenient time for skin inspection, and inquiry about the patient's inspection habits should be made. For patients using a wheelchair, walker, or other mobility device, architectural barriers to bathroom entry should be determined.

## Toileting

To the cognitively intact person, incontinence of stool or urine can be a psychologically devastating deficit of personal independence. Ineffective bowel or bladder control has an adverse impact on self-esteem, body image, and sexuality, and it can lead to participation restriction. The soiling of skin and clothing can result in ulceration, infection, and urologic complications. The physiatrist should vigorously but sensitively pursue questioning about toileting dependency.

Representative questions include the following:

1. Can you use the toilet without assistance?
2. Do you need help with clothing before or after using the toilet?
3. Do you need help with cleaning after a bowel movement?

For patients with indwelling urinary catheters, the usual management of the catheter and leg bag should be examined. If bladder emptying is accomplished by intermittent catheterization, the examiner should determine who performs the catheterization and should have a clear understanding of his or her technique. For patients who have had ostomies for urine or feces, the examiner should determine who cares for the ostomy and should ask the patient to describe the technique.

Feminine hygiene is generally performed while on or near the toilet, so at this point in the interview, it may be appropriate to ask about problems with the use of sanitary napkins or tampons.

### Dressing

We dress to go out into the world to be employed in the workplace, to dine in restaurants, to be entertained in public places, and to visit friends. Even at home, convention dictates that we dress to entertain anyone except close friends and family. We dress for protection, warmth, self-esteem, and pleasure. Dependency in dressing can result in a severe limitation to personal independence and should be investigated thoroughly during the rehabilitation interview.

Representative questions include the following:

1. Do you dress daily?
2. What articles of clothing do you regularly wear?
3. Do you require assistance putting on or taking off your underwear, shirt, slacks, skirt, dress, coat, stockings, panty hose, shoes, tie, or coat?
4. Do you need help with buttons, zippers, hooks, snaps, or shoelaces?
5. Do you use clothing modifications?

### Bed Activities

The most basic stage of functional mobility is independence in bed activities. The importance of this functional level should not be underestimated. Persons who cannot turn from side to side to redistribute pressure and periodically expose their skin to the air are at high risk for development of pressure sores over bony prominences and skin maceration from heat and occlusion. For the person who cannot stand upright to dress, bridging (lifting the hips off the bed in the supine position) will allow the donning of underwear and slacks. Independence is likewise enhanced by an ability to move between a recumbent position and a sitting position. Sitting balance is required to accomplish many other activities of daily living, including transfers.

Representative questions include the following:

1. When lying down, can you turn onto your front, back, and sides without assistance?
2. Can you lift your hips off the bed when lying on your back?
3. Do you need help to sit or lie down?
4. Do you have difficulty maintaining a seated position?
5. Can you operate the bed controls on an electric hospital bed?

### Transfers

The second stage of functional mobility is independence in transfers. Being able to move between a wheelchair and the bed, toilet, bath bench, shower chair, standard seating, or car seat often serves as a precursor to independence in other areas. Although a male patient can use a urinal to void without having to transfer, a female patient cannot be independent in bladder care without the ability to transfer to the toilet and will probably require an indwelling catheter. Travel by airplane or train is difficult without the ability to transfer from the wheelchair to other seating. Bathing or showering is not independent without the ability to move to the bath bench or shower chair. The inability to transfer to a car seat precludes the use of a motor vehicle with standard seats. Also included in this category is the ability to rise from a seated position to a standing position. Low seats without arm supports present a much greater problem than straight-backed chairs with arm supports.

Representative questions include the following:

1. Can you move to and from the wheelchair to the bed, toilet, bath bench, shower chair, standard seating, or car seat without assistance?
2. Can you get out of bed without difficulty?
3. Do you require assistance to rise to a standing position from either a low or a high seat?
4. Can you get on and off the toilet without help?

### Mobility

#### Wheelchair Mobility

Although wheelchair independence is more likely than walking to be inhibited by architectural barriers, it provides excellent mobility for the person who is not able to walk. With efficiently engineered, lightweight manual wheelchairs, the energy expenditure required to wheel on flat ground is only slightly greater than that of walking. With the addition of a motorized drive, battery power, and controls for speed and direction, a wheelchair can be propelled even by a person who lacks the upper extremity strength necessary to propel a manual wheelchair, and it can thus help maintain independence in mobility.

Quantification of manual wheelchair skills can be accomplished in several ways. Patients may report in feet, yards, meters, or city blocks the distance that they are able to traverse before resting. Alternatively, the number of minutes they can continuously propel the chair can be specified, or the environment in which they are able to use the chair can be described (e.g., within a single room, around the house, or throughout the community).

Representative questions include the following:

1. Do you propel your wheelchair yourself?
2. Do you need help to lock the wheelchair brakes before transfers?
3. Do you require assistance to cross high-pile carpets, rough ground, or inclines in your wheelchair?
4. How far or how many minutes can you wheel before you must rest?
5. Can you move independently about your living room, bedroom, and kitchen?
6. Do you go out to stores, to restaurants, and to friends' homes?

With any of these functional levels of wheelchair mobility, patients should be asked what keeps them from going farther afield and whether they need help lifting the wheelchair into and out of an automobile.

### **Ambulation**

The final level of mobility is ambulation. In the narrowest sense of the word, ambulation is walking, and we have used this definition to simplify the following discussion. However, within the sphere of rehabilitation, ambulation may be any useful means of movement from one place to another. In the view of many rehabilitation professionals, the person with a bilateral above-knee amputation ambulates with a manual wheelchair, the patient with C4 tetraplegia ambulates with a motorized wheelchair, and the survivor of polio in an underdeveloped country might ambulate by crawling. Driving a motor vehicle may also be considered a form of ambulation. Ambulation ability can be quantified the same way wheelchair mobility is quantified. Persons may report the distance they are able to walk, how long they can walk before they require a rest period, and the scope of the environment within which they walk.

Representative questions include the following:

1. Do you walk unaided?
2. Do you use a cane, crutches, or a walker to walk?
3. How far or how many minutes can you walk before you must rest?
4. What stops you from going farther?
5. Do you feel unsteady or do you fall?
6. Can you go upstairs and downstairs unassisted?
7. Do you go out to stores, to restaurants, and to friends' homes?
8. Can you use public transportation (e.g., the bus or subway) without assistance?

### **Operation of a Motor Vehicle**

In the perception of many patients, full independence in mobility is not attained without the ability to operate a motor vehicle on one's own. Although driving skills are by no means necessary for urban dwellers with readily available public transportation, they may be essential to persons living in a suburban

or rural environment. Driving skills should always be assessed in patients of driving age.

Representative questions include the following:

1. Do you have a valid driver's license?
2. Do you own a car?
3. Do you drive your car to stores, to restaurants, and to friends' homes?
4. Do you drive in heavy traffic or over long distances?
5. Do you drive in low light or after sunset?
6. Do you use hand controls or other automobile modifications?
7. Have you been involved in any motor vehicle accidents or received any citations for improper operation of a motor vehicle since your illness or injury?

### **Past Medical History**

The past medical history is a record of any major illness, trauma, or health maintenance since the patient's birth. The effects of certain past conditions will continue to affect the present level of function. Identifying these conditions affords an opportunity to better characterize the patient's baseline level of function before the present disorder. The examiner must take special care to decipher whether the patient's diagnostic terms accurately represent the true diagnoses. Although many past conditions associated with extensive immobilization, deconditioning, and disability are themselves amenable to rehabilitation measures, such conditions tend to affect the goals for future rehabilitation efforts.

### **Case 5**

PB, a 66-year-old woman, was referred for rehabilitation after an above-knee amputation of her right leg because of vascular disease. Her past history was notable for a right cerebral infarction 7 years earlier. Despite comprehensive rehabilitation after the stroke, PB was able to walk only one block with a quadruped cane and an ankle-foot orthosis because of spastic left hemiparesis.

*Comment:* After prosthetic fitting and training, most people in this age group with an above-knee amputation regain ambulation skills, albeit with a cane or other gait aid. However, because PB had a preexisting ambulation disability due to the left hemiparesis that had occurred before amputation, her rehabilitation goals included a wheelchair prescription, with consideration of a hemichair if she could not wheel with her left arm, and training in wheelchair activities. Although ambulation beyond a few yards was not feasible, a preparatory prosthesis with a manual knee lock was provided on a trial basis to determine whether it aided in transfers. For PB, ambulation disability was dictated more by her previous impairments than by impairments associated with her present illness.

All elements of the standard past medical history should be completed; however, a history of neurologic, cardiopulmonary, or musculoskeletal disease should alert the psychiatrist to special needs of the patient. Psychiatric disorders are also of

special interest to the physiatrist and are discussed below in the section on the psychological and psychiatric history.

### Neurologic Disorders

Most frequently encountered in older populations but possibly present in any age group, a past history of neurologic disease can have a tremendous impact on the rehabilitation outcome of an unrelated current illness. Whether congenital or acquired, preexisting cognitive impairment places restrictions on educationally oriented rehabilitation intervention. Disorders with sensory manifestations such as loss of touch, pain, or joint position or affections that are characterized by perceptual dysfunction can retard the patient's ability to monitor performance during the acquisition of new functional skills. These maladies also render patients more likely to be unresponsive to soft-tissue injury from prolonged or excessive skin surface pressures during long periods of immobility. When these conditions are coupled with preexisting visual or auditory impairment, the function is further encumbered. Likewise, new motor learning can be inhibited by a residual motor deficit that results in spasticity, weakness, or decreased endurance. A diligent search for antecedent neurologic disease should be a fundamental part of the rehabilitation evaluation.

### Cardiopulmonary Disorders

For patients with motor disabilities, the activities of daily living require more than the normal expenditure of energy. When preexisting cardiopulmonary disorders limit the patient's capacity to tolerate the greater energy expenditures imposed by motor impairment, they can result in additional functional deficits. This is also the case with many forms of hematologic, renal, and hepatic dysfunction. The physician should gather as much cardiopulmonary data as needed to estimate cardiac reserve accurately. Only when disease of the cardiopulmonary system is identified and addressed can medical intervention be initiated and rehabilitation tailored to maximize cardiac reserve.

### Musculoskeletal Disorders

Weakness, joint ankylosis, or instability from previous trauma or arthritis, amputation, and other musculoskeletal dysfunctions can all affect functional capacity deleteriously. A search for such disorders is a necessary prerequisite to a complete psychiatric evaluation.

### Review of Systems

The systems should be thoroughly reviewed to screen for clues to disease not otherwise identified in the history of the present illness or in the past medical history. Many diseases have the potential to cause adverse effects on rehabilitation outcomes. However, as described previously, certain disorders are of special interest to the physiatrist. This part of the evaluation considers constitutional, head and neck, respiratory, cardiovascular, gastrointestinal, genitourinary, musculoskeletal, neurologic, psychiatric, endocrine, and dermatologic symptoms.

### Constitutional Symptoms

Of particular interest to the examiner are suggestions of infection and nutritional deficiency. Fatigue can be a prominent symptom in patients with neurologic and neuromuscular conditions such as stroke, multiple sclerosis, amyotrophic lateral sclerosis, or poliomyelitis sequelae, or with other conditions such as obstructive sleep apnea or chronic pain syndromes.

### Head and Neck Symptoms

Vision, hearing, and swallowing deficits must be identified.

### Respiratory Symptoms

Any pulmonary condition that inhibits delivery of oxygen to the tissues will adversely affect endurance. Symptoms such as dyspnea, cough, sputum, hemoptysis, wheezing, and pleuritic chest pain should be identified.

### Cardiovascular Symptoms

The manifestations of heart disease restrict cardiac reserve and endurance. When identified, many cardiovascular conditions can be ameliorated through medical management. Identifying arrhythmias may help prevent recurrent strokes of embolic cause. The presence of chest pain, dyspnea, orthopnea, palpitations, or light-headedness should be determined.

Peripheral vascular disease is the leading cause of amputation. The potential for ulceration and gangrene caused by bed rest, orthoses, pressure garments, and other rehabilitation equipment can be minimized if peripheral disease is recognized. The patient should be asked about claudication, foot ulcers, and varicosities.

### Gastrointestinal Symptoms

Almost any form of gastrointestinal tract disease can result in nutritional deficiency, a particularly insidious condition that limits rehabilitation efforts more frequently than previously realized (3). Bowel control is of special interest for patients with neurologic disorders. These patients should be asked about incontinence, bowel care techniques, and use of laxatives.

### Genitourinary Symptoms

Manifestations of neurogenic bladder must be sought. Questions should be asked about specific fluid intake, voiding schedules, specific bladder-emptying techniques, urgency, frequency, incontinence, retention and incomplete emptying, sensation of fullness and voiding, dysuria, pyuria, infections, flank pain, hematuria, and renal stones.

For female patients, a menstrual and pregnancy history should be obtained, and inquiries should focus on dyspareunia, vaginal and clitoral sensation, and orgasm. Male patients should be asked about erection, ejaculation, progeny, and pain during intercourse.

### Musculoskeletal Symptoms

The musculoskeletal system review must be thorough because of the likelihood of musculoskeletal dysfunction in patients in a rehabilitation program. The examiner should ask about

muscle pain, weakness, fasciculation, atrophy, hypertrophy, skeletal deformities and fractures, limited joint motion, joint stiffness, joint pain, and swelling of soft tissues and joints.

### Neurologic Symptoms

Because of the increased prevalence of neurologic disorders in patients in a rehabilitation program, a methodical neurologic review should always be performed. The following areas should be addressed: sense of smell, diplopia, blurred vision, visual field cuts, imbalance, vertigo, tinnitus, weakness, tremors, involuntary movements, convulsions, depressed consciousness, ataxia, loss of touch, pain, temperature, dysesthesia, hyperpathia, and changes in memory and thinking.

Chewing, swallowing, hearing, reading, and speaking may be addressed in either the functional history or the review of systems.

### Psychiatric Symptoms

Psychological and psychiatric issues can be discussed during the review of symptoms. However, we prefer to explore this area while obtaining the psychosocial history for the patient profile.

### Endocrine Symptoms

Screening questions should be presented to address intolerance to hot or cold, excessive sweating, increase in urine, increase in thirst, and changes in skin, hair distribution, and voice.

### Dermatologic Symptoms

Rash, itching, pigmentation, moisture or dryness, texture, changes in hair growth, and nail changes should be questioned.

### Patient Profile

The patient profile provides the interviewer with information about the patient's present and past psychological state, social milieu, and vocational background.

### Personal History

#### *Psychological and Psychiatric History*

Any present illness accompanied by functional loss can be psychologically challenging. A quiescent major psychiatric disturbance may resurface during such stressful times and may hinder or halt rehabilitation efforts. When the examiner is able to identify a history of psychiatric dysfunction, the necessary support systems to lessen the likelihood of recrudescence can be applied prophylactically during rehabilitation. The examiner should seek a history of previous psychiatric hospitalization, psychotropic pharmacologic intervention, or psychotherapy. The patient should be screened for past or current anxiety, depression and other mood changes, sleep disturbances, delusions, hallucinations, obsessive and phobic ideas, and past major and minor psychiatric illnesses. A review of the patient's prior and current responses to stress often helps the rehabilitation team to better understand and modify behavioral responses to catastrophic illness or trauma. Therefore, it is important to know the patient's emotional responses to previous illness and family

troubles and to know how the stress of the current illness is being addressed. If initial screening suggests any abnormality, a clinical psychologist can conduct tests to clarify psychological symptoms or to identify a personality disturbance.

### *Lifestyle*

Leisure activities can promote both physical health and emotional health. The patient's leisure habits should be reviewed to identify special rehabilitation measures that might return independence in these activities. Examples of questions to consider include the following (4):

What sorts of interests do you have?

1. Do you enjoy physical endeavors, sports, the outdoors, and mechanical avocations (i.e., motor oriented) more than sedentary activities?
2. Are you more interested in intellectual pursuits (i.e., symbol oriented) than physical endeavors?
3. Do you derive the most pleasure from social interactions, organizations, and group functions (i.e., interpersonally oriented)?
4. Have you been actively pursuing any of these interests?

The work-oriented person without avocational interests before the present illness will need recreational counseling during rehabilitation.

### *Diet*

Inadequate nutrition may inhibit rehabilitation efforts. In addition, even after initial myocardial and cerebrovascular events due to atherosclerosis, some secondary prevention can be accomplished through dietary intervention. The examiner should determine the patient's ability to prepare meals and snacks, as well as the patient's usual dietary habits and special diets.

### *Alcohol and Drugs*

Drug, alcohol, and nicotine use must be assessed. Patients with cognitive, perceptual, and motor deficits can be further impaired to a dangerous degree through substance abuse. The use of alcohol or drugs is frequently a factor in head and spinal cord injuries. Identifying abuse and dependency provides an opportunity to help the patient modify future behavior through counseling. The CAGE questionnaire is a brief but useful screening vehicle for assessing alcohol abuse and dependency (Table 1-3); a single affirmative answer should initiate further investigation (5).

**TABLE 1.3** The CAGE Questionnaire

1. Have you ever felt you ought to **C**ut down on your drinking?
2. Have people **A**nnoyed you by criticizing your drinking?
3. Have you ever felt bad or **G**uilty about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or get rid of a hangover (**E**ye-opener)?

From Ewing JA. Detecting alcoholism: the CAGE questionnaire. *JAMA*. 1984;252:1905–1907, used with permission.

## Social History

### *Family*

Catastrophic illness in a family member places enormous stress on the rest of the family. When the family is already facing other problems with interaction, health, or substance abuse, the potential is greater for disintegration of the family unit. This tendency is unfortunate because the availability of a sturdy support system of family and friends can be as predictive of disposition as it is of functional outcome. The examiner should determine the patient's marriage history and marital status and should obtain the names and ages of other family members who live in the home. The established roles of each member should be understood clearly (e.g., who handles the finances, the cooking, the cleaning, or the discipline). The examiner should also determine whether other family members live nearby. To ascertain the availability of all potential assistants, the examiner should inquire about their willingness and ability to participate in the care of the patient and about their work or school schedule.

### *Home*

The patient's home design should be reviewed to identify architectural barriers. The examiner should determine whether the patient owns or rents the home, the location of the home (e.g., urban, suburban, or rural), the distance between the home and rehabilitation services, the number of steps into the home, the presence of (or room for) entry ramps, and the accessibility of the kitchen, bath, bedroom, and living room.

## Vocational History

### *Education and Training*

Although education does not predict intellectual function, the educational level achieved by the patient may suggest intellectual skills upon which the rehabilitation team can draw during the patient's convalescence. In addition, when coupled with the assessment of physical function, the educational background will dictate future educational and training needs. After determining the years of education completed by the patient and whether high school, undergraduate, or graduate degrees were obtained, the examiner should review the patient's performance. The acquisition of special skills, licenses, and certifications should be noted. Future vocational goals are always important to address but are of particular concern with adolescent patients. A discussion of these goals should indicate the need for and the type of interest, aptitude, and skills testing and any appropriate vocational counseling.

### *Work History*

An understanding of the patient's work experience can help determine the need for further education and training. It also provides an idea of the patient's motivation, reliability, and self-discipline. The duration and type of previous jobs and the reason for job changes should be recorded. Not only titles but also actual job descriptions must be obtained, and the patient should be asked about architectural barriers within

the workplace. These principles also apply to the patient who works at home. In addition, the examiner should define the specific expectations related to meal preparation, shopping, home maintenance, cleaning, child rearing, and discipline. Finally, the examiner should ask where clothes are washed and whether architectural barriers prevent the patient from reaching appliances or areas in the home and yard.

### *Finances*

The physical medicine and rehabilitation team, in particular the social worker or case manager, should have a basic understanding of the patient's income, investment, and insurance resources, disability classifications, and debts. This financial information is important in determining the services and assistance to which an individual patient may be entitled.

## Family History

The family history can be used to identify hereditary disease in the family and to assess the health of people in the patient's home support system. Knowledge of the health and fitness of the spouse and other family members can aid dismissal planning.

## PHYSICAL EXAMINATION

The physical examination performed by the physiatrist has much in common with the general medical examination. Of necessity, it is a well-practiced art. Through perceptions gleaned from observation, palpation, percussion, and auscultation, the examining physician seeks physical findings to support and formulate the diagnosis and to screen for other conditions not suggested by the patient history.

The physical examination also differs from the general medical examination. After investigating the physical findings that help to establish the medical diagnosis, the physiatrist still has two principal tasks:

1. To scrutinize the patient for physical findings that can help define the functional impairments emanating from the disease
2. To identify the patient's remaining physical, psychological, and intellectual strengths that can serve as the base for reestablishing functioning

Physical medicine and rehabilitation emphasizes the orthopedic and neurologic examinations and makes assessment of function an integral part of the overall physical examination.

Severe motor, cognitive, and communication impairments make it difficult or impossible for some patients to follow the directions of the physician, and these impairments limit certain traditional physical examination maneuvers. Thus, creativity is often required to accomplish the examination. Expert examination skills are particularly necessary in such situations.

We assume that the reader is competent in the performance of the general medical examination (6). The following discussion places priority on the aspects of the physical examination that have special relevance to physical medicine

and rehabilitation. The major segments of the physical examination are vital signs and general appearance, integument and lymphatics, head, eyes, ears, nose, mouth and throat, neck, chest, heart and peripheral vascular system, abdomen, genitourinary system and rectum, musculoskeletal system, neurologic examination, and functional examination.

### **Vital Signs and General Appearance**

The recording of blood pressure, pulse, temperature, weight, and general observations is important. The identification of hypertension may be meaningful to the secondary prevention of stroke and myocardial infarction. Supine, sitting, and standing blood pressures should be obtained to rule out orthostasis in any patient who has had unexplained falls, light-headedness, or dizziness. Tachycardia can be the initial manifestation of sepsis in a patient with high-level tetraplegia, or it can suggest pulmonary embolism in an immobilized patient. Initial weight recordings are invaluable to identify and follow up malnutrition, obesity, and fluid and electrolyte disorders common after various forms of brain injury. A notation should be made if patients act hostile, tense, or agitated or if their behavior is uncooperative, inappropriate, or preoccupied.

### **Integument and Lymphatics**

Skin disorders are frequently encountered in patients undergoing physical rehabilitation. Prolonged pressure in patients with peripheral vascular disease, sensory disorders, immobility, and altered consciousness often results in damage to skin and underlying tissues. Many diseases common to disabled persons, and their treatments, render the skin more prone to trauma and infection. Skin problems that are only somewhat bothersome to able-bodied people can be devastating to persons with disabilities when they interfere with the use of prostheses, orthoses, and other devices.

The patient's skin should be inspected in appropriate lighting. By considering the skin as each separate body region is examined, the psychiatrist can study the entire body surface without total exposure of the patient. In particular, the skin over bony prominences and in contact with prosthetic and orthotic devices should be examined for lichenification, erythema, or breakdown. Intertriginous areas should be inspected for maceration and ulceration; the distal lower extremities in patients with vascular disease should be examined for pigmentation, hair loss, and breakdown; and the hands and feet in insensate patients should be observed for unrecognized trauma. All common lymph node sites should be palpated for enlargement and tenderness, and areas of edema should be palpated for pitting.

### **Head**

The head should be inspected for signs of past or present trauma. Gentle palpation should be performed for evidence of previous trauma or neurosurgical procedures, shunt pumps, and other craniofacial abnormalities. Auscultation for bruits should be done when considering vascular malformations.

### **Eyes**

Unrecognized acuity errors can hamper rehabilitation efforts, especially in patients needing adequate eyesight to compensate for disorders of other sensory systems. With the patient's usual eyewear in place, far and near vision should be tested with the use of standard charts. If charts are not available, the patient's vision can be compared with the examiner's vision by object identification and description for far vision and by reading materials of several print sizes for near vision. Findings can be substantiated with refraction when circumstances permit. An ophthalmoscopic examination should be performed; if dilatory agents are necessary, one with a short duration can be used; notation should be made in the patient's chart of the time of administration and the name of the preparation. Evidence of erythema and inflammation of the globe or conjunctiva should be sought; aphasic patients and those with altered consciousness may not adequately express the pain of acute glaucoma or the discomfort of conjunctivitis. The eyes of comatose patients should be inspected for inadequate lid closure; deficient lubrication should be compensated for to prevent corneal ulcerations.

### **Ears**

Unrecognized hearing impairment can limit rehabilitation efforts. Hearing acuity can be checked with the "watch test" or by having the patient listen to and repeat words that are whispered. If a unilateral hearing deficit is identified, the Weber test and the Rinne test can be used to determine whether it is a nerve or conductive loss. Findings can be substantiated with an audiogram. An otoscopic examination should be performed. If otorrhea is present in a head-injured patient, Benedict solution can be used to assess the presence of sugar, which indicates cerebrospinal fluid.

### **Nose**

A routine examination of the nose, including olfactory function, is generally sufficient. Clear or blood-tinged drainage in a head-injured patient indicates the presence of cerebrospinal fluid.

### **Mouth and Throat**

The oral and pharyngeal mucosa should be inspected for poor hygiene and infections (e.g., candidiasis in patients taking corticosteroids or broad-spectrum antibiotics), the teeth for disrepair, and the gums for gingivitis or hypertrophy. Dentures should be checked for fit and maintenance. In patients with arthritis or trauma, the temporomandibular joints should be inspected and palpated for crepitation, tenderness, swelling, or limited motion. Any of these problems can impair food and fluid intake, resulting in poor nutrition.

### **Neck**

A routine examination of the neck is generally sufficient. The examiner should listen for carotid bruits in patients with atherosclerosis and cerebrovascular disorders. In patients with musculoskeletal disorders, range of motion (ROM) should be assessed. However, neck motion need not be checked in

patients with recent trauma or chronic polyarthritides until radiographic studies have ruled out fracture or instability.

## Chest

Tolerance to exercise is considerably affected by pulmonary function. For patients whose exercise tolerance is already compromised by neurologic or musculoskeletal disease, the examiner must search rigorously for pulmonary dysfunction to minimize the deficit. The standard medical maneuvers are usually sufficient; however, certain aspects of the chest examination merit mention.

The chest wall should be inspected to note the rate, amplitude, and rhythm of breathing. The presence of cough, hiccups, labored breathing, accessory muscle activity, and chest wall deformities should be noted. Respiration may be restricted by rheumatologic disorders such as advanced spondyloarthropathies and scleroderma. Likewise, restrictive pulmonary disease with hypoventilation is common in muscular dystrophy and other neuromuscular diseases, severe kyphoscoliosis, and chronic spinal cord injuries. Tachypnea and tachycardia may be the only readily apparent manifestations of pulmonary embolism, pneumonia, or sepsis after a high-level spinal cord injury. The finding of a barrel chest may lead the examiner to identify obstructive pulmonary disease so that medical management can minimize its effect on functioning.

The patient should be instructed to cough, and the force and efficiency of this action should be noted. If the cough is weak, the patient can be assisted by exerting manual pressure over the abdomen coincidentally with the cough to observe the effect. The chest wall should be palpated for tenderness, deformity, and transmitted sounds. During the acute care of a head-injured patient, rib fractures may be missed. Percussion should be performed to document diaphragmatic level and excursion. Auscultation should be performed to characterize breath sounds and to identify wheezes, rales, rhonchi, and rales. Pneumonitis can be especially insidious in the immunosuppressed patient.

When pulmonary disease is suspected, further investigation with pulmonary function tests and a determination of blood gas levels may need to be undertaken. If the patient has a tracheostomy, the skin around the opening should be examined, the type of apparatus recorded, and cuff leaks noted. Screening for breast malignancy may be necessary in women and men alike.

## Heart and Peripheral Vascular System

As with pulmonary disease, cardiovascular dysfunction can adversely affect exercise tolerance already encumbered by neurologic or musculoskeletal disease. When cardiovascular disorders are identified, intervention can relieve or reduce deleterious effects on exercise tolerance and general health. Implementation of appropriate secondary prevention measures for embolic stroke is contingent upon the identification of arrhythmias, valvular disease, and congenital anomalies.

In the clinical situation, peripheral circulation is usually assessed during examination of the patient's limbs. When bracing is being considered, the examiner should search for the

pallor and cool dystrophic skin of arterial occlusive disease; inappropriate devices may lead to edema and subsequent skin breakdown. Deep venous thrombosis is a major risk to immobilized patients, who should be examined for varicose and incompetent veins. Bedside Doppler studies should be used as necessary to help delineate arterial or venous concerns such as Raynaud phenomenon.

## Abdomen

In many patients, the general medical examination of the abdomen is the only necessary screen to identify abnormality and to assess gastrointestinal tract symptoms. In patients with widespread spasticity (e.g., due to multiple sclerosis or myelopathy), inspection and auscultation should precede palpation and percussion. Manipulation of the abdominal wall often results in a wave of increased tone that will temporarily impede the rest of the abdominal examination. Vigorous abdominal palpation in patients with disordered peristalsis from certain central nervous system diseases may initiate regurgitation of stomach contents. Such patients should be examined gently when they are in a partially reclined position.

## Genitourinary System and Rectum

During any comprehensive evaluation, the genitalia should be examined. A thorough evaluation of the male and female genitalia is particularly necessary for patients with disorders of continence, micturition, and sexual function. Incontinence in patients of either sex and in male patients using an external collecting device such as the condom catheter can result in maceration and ulceration. Thus, the penile skin in male patients, the periurethral mucosa in female patients, and all intertriginous perineal areas should be examined. The scrotal contents should be palpated for orchitis and epididymitis in male patients with indwelling catheters. Incontinence from neurogenic causes is common in patients undergoing rehabilitation; however, the examiner should check for a cystocele or other structural cause of incontinence that can be remediated. Patients with long-term use of indwelling catheters should be checked for external urethral meatal ulceration, and male patients should be checked for penile fistulas. If urinary retention is suspected, the physical examination should be followed by an in-and-out catheterization to measure residual urine.

The rehabilitation assessment is not complete without digital examination of the rectum and anus to check anal tone and perineal sensation. In any patient with suspected central nervous system, autonomic, or pelvic disease, the bulbocavernosus reflex should be evaluated to monitor sphincter tone by firmly compressing the glans of the penis or clitoris with one hand while inserting the index finger of the other hand into the anus. Sphincter tone is increased with many upper motor neuron lesions, whereas it is decreased or absent with lesions peripheral to the sacral cord (S2-4).

## Musculoskeletal System

Disorders of the musculoskeletal system are a major portion of the pathologic conditions addressed by the rehabilitation

physician. The examiner must possess expert skills in the evaluation of all musculoskeletal components and should systematically assess the bone, joint, cartilage, ligament, tendon, and muscle in each body region. Accomplishing this task requires full familiarity with surface landmarks and underlying anatomical features.

The assignment of many examination components to the neurologic or musculoskeletal examination is arbitrary because the neuromusculoskeletal function is so integrated. Examination of the musculoskeletal system is divided into inspection, palpation, ROM assessment, joint stability assessment, and muscle strength testing.

### Inspection

Musculoskeletal inspection should be performed for scoliosis, abnormal kyphosis, and lordosis; joint deformity, amputation, absence and asymmetry of body parts (leg-length discrepancy); soft-tissue swelling, mass, scar, and defect; and muscle fasciculations, atrophy, hypertrophy, and rupture. At times, the dysfunction may be subtle and decipherable only through careful observation. While proceeding with the examination, the physician should note any wary and tentative movements of the patient indicative of pain, any exaggerated and inconsistent conduct indicative of malingering, and any bizarre behavior indicative of conversion reaction.

### Palpation

Localized abnormalities (e.g., areas of tenderness or deformity) identified through inspection and any body regions of concern to the patient should be palpated to ascertain their structural origins. For an abnormality, it is important to first determine whether its basic consistency is that of soft tissue or bone and whether it is of normal anatomical structure. An attempt should be made to further identify soft-tissue abnormalities as pitting or nonpitting edema, synovitis, or mass lesions.

All skeletal elements near areas of hemorrhage and ecchymosis in patients with altered consciousness should be palpated. The elderly patient with traumatic subdural hematoma may

have an extremity fracture associated with a fall. During the critical care of a motorcyclist with a head injury, an incidental fracture may have been missed. Likewise, any in-hospital fall by a confused patient warrants a search for occult bony trauma.

### ROM Assessment

Human joint motion is measured during clinical evaluation by many health care professionals for various reasons, including initial evaluation, evaluation of treatment procedure, feedback to the patient, assessment of work capacity, or research studies. When identifying a starting point for measuring the ROM of a joint, we prefer to regard the anatomical position as the baseline (zero starting point). If rotation is being measured, the midway point between the normal rotation range should be the zero starting point (7).

Considerable variation exists among the ROM measurements of different persons. Factors such as age, sex, conditioning, obesity, and genetics can influence the normal ROM. The American Academy of Orthopaedic Surgeons has reported the average ROM measurements for joints in the human body (8).

When the patient does not assist the examiner during an assessment, the measurement is a passive ROM. If the patient performs the ROM maneuver without assistance, then the range is an active ROM. If comparisons are made between active and passive ROMs, the starting position, stabilization, goniometer, alignment, and type of goniometer should be the same.

Different methods are available for recording the results of ROM measurements. Graphic recordings are often helpful for providing feedback to the patient or a third party. Sometimes the difference between the patient's ROM and a normal ROM is of special interest to the examiner, such as when the surgeon wants to evaluate finger motion periodically as a guide to recovery after a hand operation.

The goniometer position, starting position, and average ROM of the more commonly measured joints are shown in Figures 1-1 through 1-26.

Axis through knee joint  
Shaft along midthigh  
Shaft along fibula

**FIGURE 1-24.** Knee flexion. Starting position: Prone (or supine with hip flexed if rectus femoris limits motion). Measurement: Sagittal plane. Goniometer: Axis through knee joint; shaft along midthigh; shaft along fibula. (Courtesy of J.F. Lehmann, MD.)

**Starting position**

Sitting  
Knee flexed to 90°  
Foot at 90° angle to leg

**Measurement**

Sagittal plane  
Goniometer:  
Axis on sole of foot  
Shaft along fibula  
Shaft along fifth metatarsal bone

**FIGURE 1-25.** Ankle dorsiflexion. Starting position: Sitting, knee flexed to 90 degrees, foot at 90-degree angle to leg. Measurement: Sagittal plane. Goniometer: Axis on sole of foot; shaft along fibula; shaft along fifth metatarsal bone. (Courtesy of J.F. Lehmann, MD.)

**Starting position**

Same as in Figure 1-25

**Measurement**

Same as in Figure 1-25

**FIGURE 1-26.** Ankle plantar flexion. Starting position: Same as in Figure 1-25. Measurement: Same as in Figure 1-25. (Courtesy of J.F. Lehmann, MD.)

**Joint Stability Assessment**

Joint stability is the capacity of the structural elements of a joint to resist the forces of an inappropriate vector. It is determined by the degree of bony congruity, cartilaginous and capsular integrity, and ligament and muscle strength and by the forces applied to the joint. For example, the ball-and-socket arrangement of the hip joint is inherently stable because of bony congruity, whereas the glenohumeral joint must rely on musculoligamentous support because of the incongruity of the spherical humeral head in relation to the shallow curve of the glenoid fossa.

Joint stability is often compromised by disorders commonly treated by physical medicine and rehabilitation staff. For example, inflammatory synovitis associated with polyarthritis weakens the joint capsule and surrounding ligaments, and the resulting pain inhibits muscle contraction. This inhibition renders the involved joint susceptible to trauma from normal and abnormal forces and leads to joint instability. Similarly, traumatic and neurogenic conditions may commonly result in instability of peripheral and axial joints.

Excessive joint motion is often identified during the ROM assessment. However, several specialized physical examination maneuvers (e.g., the Larson test, the Lachman test, or the pivot shift test) can be used to assess individual joint integrity. Although a discussion of these tests is beyond the scope of this chapter, excellent texts are available on them (6,9,10).

The stability of each joint should be assessed in an orderly fashion. A routine series of individual joint maneuvers should be used as part of the general examination, and additional tests should be performed as necessary to identify more subtle instability when indicated by the history or general examination.

If joint instability is recognized or suspected during the physical examination, subsequent radiographic studies can often be helpful for quantifying the extent of instability. At times, flexion-extension views of the spine and stressed joint views of extremity joints can be informative; however, these should not be considered until the physical examination and nonstressed films have determined that such maneuvers are safe.

### Muscle Strength Testing

Manual muscle testing provides an important means of assessing strength but also can be used to assess weakness. The examiner should keep in mind many factors that can affect the effort a patient is able to put into the testing. These factors include age, sex, pain, fatigue, low motivation, fear, misunderstanding of the test, and the presence of lower or upper motor neuron disease.

Lower motor neuron disease results in patterns of motor loss that depend on the location of the disease. For example, peripheral neuropathy results in a pattern of weakness in the muscles supplied by the affected nerve, whereas poliomyelitis results in residual weakness that is often scattered. The flaccid characteristic of a paretic muscle or muscle group in lower motor neuron disease allows the testing procedure to be uncomplicated by the spasticity or rigidity of upper motor neuron disease. Knowledge of the appearance of the muscle surface when a muscle undergoes atrophy from lower motor neuron disease also can be helpful to the clinician. If the joint crossed by the muscle being tested is unstable because of a chronic flaccid state, the grade of weakness may be difficult to estimate.

Upper motor neuron disease frequently results in spastic muscles that make manual testing challenging. For example, the antagonist muscle may be spastic and resist the action of the muscle being tested, or contractures may have developed that complicate the testing by limiting the available ROM.

Detailed discussions of the technique of manual muscle testing can be found in the publications of Kendall et al. (11) and Hislop and Montgomery (12). The anatomical basis for manual muscle testing of the major groups of muscles is discussed below (1).

## ANATOMICAL INFORMATION REQUIRED TO TEST INDIVIDUAL MUSCLE STRENGTH

In the description of each test below, which is based on the format used in *Mayo Clinic Examinations in Neurology* (1), the name of each muscle is followed by the corresponding peripheral nerve and spinal segmental supply. Different authorities give considerable variability in segmental supply, particularly for certain muscles. Anatomical variation also exists both in the plexus and in the peripheral nerves.

Therefore, the segments listed here cannot be regarded as absolute. The “action” sections identify only the principal and important secondary or accessory functions that are useful in testing. The positions and the movements in each test refer first to the patient. When the movement is adequately indicated by the action of the muscle, it has been omitted here. Unless otherwise stated, “resistance” refers to pressure applied by the examiner in the opposite direction of the patient’s movement. For brevity and uniformity, we have given methods of testing that involve the patient initiating action against the resistance of the examiner, except when the other method is distinctly more applicable, but we do not mean to imply a preference for this method. We have often given the location of the belly of the muscle and its tendon so as to stress the importance of observation and palpation in identifying the muscle’s function. We have listed only those participating muscles with a definite action in the movement being tested that may substitute in part or in whole for the muscle being reviewed.

The following text has been adapted with permission from the Mayo Foundation for Medical Education and Research (1).

### Trapezius

Spinal accessory nerve (Fig. 1-27).

#### Action

Elevation, retraction (adduction), and rotation (lateral angle upward) of the scapula, providing fixation of the scapula during movement of the arm.

**FIGURE 1-27.** Upward rotators of the scapula. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:99. Used with permission of Mayo Foundation for Medical Education and Research.)

**Test**

1. Elevation (shrugging) of the shoulder against resistance tests the upper portion, which is readily visible.
2. Bracing the shoulder (backward movement and adduction of the scapula) primarily tests the middle portion.
3. Abduction of the arm against resistance intensifies the winging of the scapula that may be present in paresis of the trapezius muscle (as in spinal accessory neuropathy).

In isolated trapezius palsy with the shoulder girdle at rest, the scapula is displaced downward laterally and rotated so that the superior angle is farther from the spine than the inferior angle. The lateral displacement is due in part to the unopposed action of the serratus anterior. The vertebral border, particularly at the inferior angle, is flared. These changes are accentuated when the arm is abducted from the side against resistance. On flexion (forward elevation) of the arm, however, this flaring of the inferior angle virtually disappears. These features are important in distinguishing paresis of the trapezius from that of the serratus anterior, because both conditions produce winging of the scapula.

**Participating Muscles**

1. Elevation: levator scapulae (third and fourth cervical nerves and dorsal scapular nerve, C3-5).
2. Retraction: rhomboids.
3. Upward rotation: serratus anterior.

**Rhomboids (Fig. 1-28)**

Dorsal scapular nerve from the anterior ramus, C4, C5 (Fig. 1-29).

**FIGURE 1-28.** Musculature of the shoulder, posterior view. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:89. Used with permission of Mayo Foundation for Medical Education and Research.)

**Action**

Retraction (adduction) of the scapula and elevation of its vertebral border.

**Test**

The hand is on the hip; the arm is held backward and rotated medially. The examiner attempts to force the patient's elbow laterally and forward while observing and palpating the muscle bellies medial to the scapula.

**Participating Muscles**

Trapezius; levator scapulae with elevation of the medial border of the scapula.

**Serratus Anterior (see Fig. 1-27)**

Long thoracic nerve from the anterior rami, C5-7 (see Fig. 1-29). See Appendix A.

**Action**

1. Protraction (lateral and forward movement) of the scapula while it is kept close to the thorax.
2. Assistance in the upward rotation of the scapula.

**FIGURE 1-29.** Brachial plexus. (From Haymaker W, Woodhall B, eds. *Peripheral Nerve Injuries: Principles of Diagnosis*. 2nd ed. Philadelphia, PA: WB Saunders Company; 1953:210, used with permission.)

**Test**

The patient's outstretched arm is thrust forward against a wall or against resistance provided by the examiner.

Isolated palsy results in comparatively little change in the appearance of the shoulder girdle at rest. However, there is slight winging of the inferior angle of the scapula and a slight shift medially toward the spine. When the outstretched arm is thrust forward, the entire scapula, particularly its inferior angle, shifts backward away from the thorax, producing the characteristic wing effect. Abduction of the arm laterally, however, produces comparatively little winging, compared with the manifestations of paralysis of the trapezius.

**Supraspinatus (Fig. 1-30)**

Suprascapular nerve from the upper trunk of the brachial plexus, C5, C6 (see Fig. 1-29). See Appendix B.

**Action**

Initiation of abduction of the arm from the side of the body.

**Test**

The above action is tested against resistance.

Atrophy may be detected just above the spine of the scapula, but the trapezius overlies the supraspinatus, and atrophy of either muscle will produce a depression in this area. Scapular fixation is important in this test.

**Participating Muscle**

Deltoid.

**FIGURE 1-30.** Abductors of the arm. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:103. Used with permission of Mayo Foundation for Medical Education and Research.)

**FIGURE 1-31.** The chief lateral rotators of the arm. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:106. Used with permission of Mayo Foundation for Medical Education and Research.)

**Infraspinatus (Fig. 1-31)**

Suprascapular nerve from the upper trunk of the brachial plexus, C5, C6 (see Fig. 1-29). See Appendix B.

**Action**

Lateral (external) rotation of the arm at the shoulder.

**Test**

The elbow is at the side and flexed 90 degrees. The patient resists the examiner's attempt to push the hand medially toward the abdomen.

The muscle is palpable, and atrophy may be visible below the spine of the scapula.

**Participating Muscles**

Teres minor (axillary nerve); deltoid (posterior fibers).

**Pectoralis Major (Fig. 1-32)**

See Figure 1-29 and Appendix A.

1. Clavicular portion (lateral pectoral nerve from the lateral cord of the plexus, C5-7).
2. Sternal portion (medial pectoral nerve from the medial cord of the plexus, lateral pectoral nerve, C6-8, T1).

**FIGURE 1-32.** The pectoral (shaded) and related muscles. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:85. Used with permission of Mayo Foundation for Medical Education and Research.)

### Action

1. Adduction and medial rotation of the arm.
2. Clavicular portion: assistance in flexion of the arm.

### Test

1. The arm is in front of the body. The patient resists the examiner's attempt to force it laterally.
2. The two portions of the muscle are visible and palpable.

### Latissimus Dorsi (Fig. 1-33)

Thoracodorsal nerve from the posterior cord of the plexus, C6-8 (see Fig. 1-29). See Appendix C.

### Action

Adduction, extension, and medial rotation of the arm.

### Test

The arm is in abduction to the horizontal position. Downward and backward movement against resistance is applied under the elbow.

The muscle should be observed and palpated in and below the posterior axillary fold. When the patient coughs, a brisk contraction of the normal latissimus dorsi can be felt at the inferior angle of the scapula.

### Teres Major (Fig. 1-33A)

Lower subscapular nerve from the posterior cord of the plexus, C5-7 (see Fig. 1-29). See Appendix C.

### Action

Same as for the latissimus dorsi.

### Test

Same as for the latissimus dorsi. The muscle is visible and palpable at the lower lateral border of the scapula.

### Deltoid (Fig. 1-33C; see Fig. 1-32)

Axillary nerve from the posterior cord of the plexus, C5, C6 (see Fig. 1-29). See Appendix D.

### Action

1. Abduction of the arm.
2. Flexion (forward movement) and medial rotation of the arm: anterior fibers.
3. Extension (backward movement) and lateral rotation of the arm: posterior fibers.

### Test

1. The arm is almost horizontal in abduction. The patient resists the examiner's efforts to depress the elbow. Paralysis of the deltoid leads to conspicuous atrophy and serious disability, because the other muscles that participate in abduction of the arm (the supraspinatus, trapezius, and serratus anterior—the last two by rotating the scapula) cannot compensate for the deltoid's lack of function.
2. Flexion and extension of the arm are tested against resistance.

### Participating Muscles

1. Abduction: given above.
2. Flexion: pectoralis major (clavicular portion); biceps.
3. Extension: latissimus dorsi; teres major.

### Subscapularis (Fig. 1-33B)

Upper and lower subscapular nerves from the posterior cord of the plexus, C5-7 (see Fig. 1-29). See Appendix C.

### Action

Medial (internal) rotation of the arm at the shoulder.

**FIGURE 1-33.** The chief medial rotators of the arm. **A:** posterior view; **B** and **C:** anterior views. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:105. Used with permission of Mayo Foundation for Medical Education and Research.)

### Test

The patient's elbow is at the side and flexed 90 degrees. The patient resists the examiner's attempt to pull the hand laterally.

Because this muscle is not accessible to observation or palpation, it is necessary to gauge the activity of other muscles that produce this movement. The pectoralis major is the most powerful medial rotator of the arm; hence, paralysis of the subscapularis alone results in relatively little weakness of this movement.

### Participating Muscles

Pectoralis major; deltoid (anterior fibers); teres major; latissimus dorsi.

### Biceps; Brachialis (Fig. 1-34)

Musculocutaneous nerve from the lateral cord of the plexus, C5, C6 (see Fig. 1-29).

### Action

1. Biceps: flexion and supination of the forearm and assistance in flexion of the arm at the shoulder.
2. Brachialis: flexion of the forearm at the elbow.

### Test

Flexion of the forearm is tested against resistance. The forearm should be in supination to decrease participation of the brachioradialis.

### Triceps (Fig. 1-35)

Radial nerve, which is a continuation of the posterior cord of the plexus, C6-8 (see Fig. 1-29). See Appendix C.

**FIGURE 1-34.** The flexors of the forearm. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:129. Used with permission of Mayo Foundation for Medical Education and Research.)

**FIGURE 1-35.** Posterior muscles of the right arm. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:122. Used with permission of Mayo Foundation for Medical Education and Research.)

### Action

Extension of the forearm at the elbow.

### Test

The forearm is in flexion to varying degrees. The patient resists the examiner's effort to flex the forearm farther. Slight weakness is more easily detected when starting with the forearm almost completely flexed.

### Brachioradialis (Fig. 1-36)

Radial nerve, C5, C6 (see Fig. 1-29). See Appendix E.

### Action

Flexion of the forearm at the elbow.

### Test

Flexion of the forearm is tested against resistance, with the forearm midway between pronation and supination. The belly of the muscle stands out prominently on the upper surface of the forearm, tending to bridge the angle between the forearm and the arm.

**FIGURE 1-36.** Supinators of the forearm. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:173. Used with permission of Mayo Foundation for Medical Education and Research.)

### Participating Muscles

Biceps; brachialis.

### Supinator (see Fig. 1-36)

Posterior interosseous nerve from the radial nerve, C5, C6 (see Fig. 1-29). See Appendix E.

### Action

Supination of the forearm.

### Test

The forearm is in full extension and supination. The patient tries to maintain supination while the examiner attempts to pronate the forearm and palpate the biceps.

Resistance to pronation by the intact supinator can usually be felt before there is appreciable contraction of the biceps.

**FIGURE 1-37.** Extensors at the wrist. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:174. Used with permission of Mayo Foundation for Medical Education and Research.)

### Extensor Carpi Radialis Longus (Fig. 1-37)

Radial nerve, C6, C7 (see Fig. 1-29). See Appendix E.

#### Action

Extension (dorsiflexion) and radial abduction of the hand at the wrist.

#### Test

The forearm is in almost complete pronation. Dorsiflexion of the wrist is tested against resistance applied to the dorsum of the hand downward and toward the ulnar side.

The tendon is palpable just above its insertion into the base of the second metacarpal bone. To minimize participation of the extensors of the digits, the patient should relax the fingers and thumb but flex them somewhat.

### Extensor Carpi Radialis Brevis (see Fig. 1-37)

Posterior interosseous nerve from the radial nerve, C6, C7 (see Fig. 1-29). See Appendix E.

#### Action

Extension (dorsiflexion) of the hand at the wrist.

#### Test

The forearm is in complete pronation. Dorsiflexion of the wrist is tested against resistance applied straight downward to the dorsum of the hand.

The tendon is palpable just proximal to the base of the third metacarpal bone. To minimize participation of the extensors of the digits, the patient should relax the fingers and thumb but flex them somewhat.

### Extensor Carpi Ulnaris (see Fig. 1-37)

Posterior interosseous nerve from the radial nerve, C7, C8 (see Fig. 1-29). See Appendix E.

#### Action

Extension (dorsiflexion) and ulnar deviation of the hand at the wrist.

#### Test

The forearm is in pronation. Dorsiflexion and ulnar deviation of the wrist are tested against resistance applied to the dorsum of the hand downward and toward the radial side.

The tendon is palpable just below or above the distal end of the ulna. To minimize participation of the extensors of the digits, the patient should relax the fingers but flex them somewhat.

### Extensor Digitorum Communis (see Fig. 1-37)

Posterior interosseous nerve from the radial nerve, C7, C8 (see Fig. 1-29). See Appendix E.

#### Action

1. Extension of the fingers, principally at the metacarpophalangeal joints.
2. Assistance in extension (dorsiflexion) of the wrist.

#### Test

The forearm is in pronation. The wrist is stabilized in a straight position. Extension of the fingers at the metacarpophalangeal joints is tested against resistance applied to the proximal phalanges.

The distal portions of the fingers may be somewhat relaxed but slightly flexed. The tendons are visible and palpable over the dorsum of the hand.

Extension at the interphalangeal joints is a function primarily of the interossei (ulnar nerve) and the lumbricals (median and ulnar nerves).

To minimize the action of the common extensor, the physiatrist can individually test the extensor digiti quinti and extensor indicis (posterior interosseous nerve, C7, C8), which

are proper extensors of the little finger and the index finger, respectively, while the other fingers are flexed. In a thin person's hand, these tendons can usually be identified.

### **Abductor Pollicis Longus (see Fig. 1-36)**

Posterior interosseous nerve from the radial nerve, C7, C8. See Appendix E.

#### **Action**

1. Radial abduction of the thumb (in the same plane as that of the palm, in contradistinction to palmar abduction, which is movement perpendicular to the plane of the palm).
2. Assistance in radial abduction and flexion of the hand at the wrist.

#### **Test**

1. The hand is on the edge (the forearm is midway between pronation and supination).
2. Radial abduction of the thumb is tested against resistance applied to the metacarpal.

The tendon, which forms the anterior (volar) boundary of the “anatomic snuffbox,” is palpable just above its insertion into the base of the metacarpal bone.

#### **Participating Muscle**

Extensor pollicis brevis.

### **Extensor Pollicis Brevis**

Posterior interosseous nerve from the radial nerve, C7, C8. See Appendix E.

#### **Action**

1. Extension of the proximal phalanx of the thumb.
2. Assistance in radial abduction and extension of the metacarpal of the thumb.

#### **Test**

The hand is on the edge. The wrist and the metacarpal of the thumb are stabilized by the examiner. Extension of the proximal phalanx is tested against resistance applied to that phalanx, while the distal phalanx is in flexion to minimize the action of the extensor pollicis longus.

At the wrist, the tendon lies just posterior (dorsal) to the tendon of the abductor pollicis longus.

#### **Participating Muscle**

Extensor pollicis longus.

### **Extensor Pollicis Longus (see Fig. 1-37)**

Posterior interosseous nerve from the radial nerve, C7, C8. See Appendix E.

#### **Action**

1. Extension of all parts of the thumb but specifically extension of the distal phalanx.
2. Assistance in adduction of the thumb.

#### **Test**

The hand is on the edge. The wrist and the metacarpal and proximal phalanx of the thumb are stabilized by the examiner, with the thumb close to the palm at its radial border. Extension of the distal phalanx is tested against resistance.

If the patient is permitted to flex the wrist or abduct the thumb away from the palm, some extension of the phalanges results simply from lengthening the path of the extensor tendon. At the wrist, the tendon forms the posterior (dorsal) boundary of the anatomic snuffbox.

The characteristic result of radial nerve palsy is wrist-drop. Extension of the fingers at the interphalangeal joints is still possible by virtue of the action of the interossei and lumbricals, but extension of the thumb is lost.

### **Pronator Teres (Fig. 1-38)**

Median nerve, C6, C7 (see Fig. 1-29). See Appendix F.

**FIGURE 1-38.** Pronators of the forearm. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:172. Used with permission of Mayo Foundation for Medical Education and Research.)

**Action**

Pronation of the forearm.

**Test**

The elbow is at the side of the trunk, the forearm is in flexion to the right angle, and the arm is in lateral rotation at the shoulder to eliminate the effect of gravity, which favors pronation in most positions. Pronation of the forearm is tested against resistance, starting from a position of moderate supination.

**Participating Muscle**

Pronator quadratus (anterior interosseous branch of the median nerve, C7, C8, T1).

**Flexor Carpi Radialis (Figs. 1-38 and 1-39)**

Median nerve, C6, C7 (see Fig. 1-29). See Appendix F.

**Action**

1. Flexion (palmar flexion) of the hand at the wrist.
2. Assistance in radial abduction of the hand.

**FIGURE 1-39.** Flexors at the wrist. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:174. Used with permission of Mayo Foundation for Medical Education and Research.)

**Test**

1. Flexion of the hand is tested against resistance applied to the palm.
2. The fingers should be relaxed to minimize participation of their flexors. The tendon is the more lateral (radial) of the two conspicuous tendons on the volar aspect of the wrist.

In complete median nerve palsy, flexion of the wrist is considerably weakened but can still be performed by the flexor carpi ulnaris (ulnar nerve), assisted to some extent by the abductor pollicis longus (radial nerve). In this event, ulnar deviation of the hand usually accompanies flexion.

**Palmaris Longus (see Fig. 1-39)**

Median nerve, C7, C8, T1 (see Fig. 1-29). See Appendix F.

**Action**

Flexion of the hand at the wrist.

**Test**

Same as that for flexor carpi radialis. The tendon is palpable at the ulnar side of the tendon of the flexor carpi radialis.

**Flexor Carpi Ulnaris (see Fig. 1-39)**

Ulnar nerve, C7, C8, T1 (see Fig. 1-29). See Appendix G.

**Action**

1. Flexion and ulnar deviation of the hand at the wrist.
2. Fixation of the pisiform bone during contraction of the abductor digiti quinti.

**Test**

Flexion and ulnar deviation of the hand are tested against resistance applied to the ulnar side of the palm in the direction of extension and radial abduction. The fingers should be relaxed. The tendon is palpable proximal to the pisiform bone.

**Flexor Digitorum Superficialis (see Fig. 1-39)**

Median nerve, C7, C8 (see Fig. 1-29). See Appendix F.

**Action**

1. Flexion primarily of the middle phalanges of the fingers at the first interphalangeal joints; flexion secondarily of the proximal phalanges at the metacarpophalangeal joints.
2. Assistance in flexion of the hand at the wrist.

**Test**

The wrist is in a neutral position; the proximal phalanges are stabilized. Flexion of the middle phalanx of each finger is tested against resistance applied to that phalanx, with the distal phalanx relaxed.

**Flexor Digitorum Profundus**

See Figure 1-39 and Appendices F and G.

**FIGURE 1-40.** Short muscles of the thumb and little finger (dark shading), and flexor tendon sheaths of the hand (light shading). (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:187. Used with permission of Mayo Foundation for Medical Education and Research.)

1. Radial portion: usually to digits II and III (median nerve and its anterior interosseous branch C7, C8, T1).
2. Ulnar portion: usually to digits IV and V (ulnar nerve, C7, C8, T1).

#### Action

1. Flexion primarily of the distal phalanges of the fingers; flexion secondarily of other phalanges.
2. Assistance in flexion of the hand at the wrist.

#### Test

1. Flexion of the distal phalanges is tested against resistance, with the proximal and middle phalanges stabilized in extension.
2. With the middle and distal phalanges folded over the edge of the examiner's hand, the patient resists the examiner's attempt to extend the distal phalanges.

#### Flexor Pollicis Longus (see Fig. 1-39)

Anterior interosseous branch of the median nerve, C7, C8, T1. See Appendix F.

#### Action

1. Flexion of the thumb, particularly the distal phalanx.
2. Assistance in ulnar adduction of the thumb.

#### Test

Flexion of the distal phalanx is tested against resistance, with the thumb in the position of palmar adduction and with stabilization of the metacarpal and the proximal phalanx.

#### Abductor Pollicis Brevis (Fig. 1-40)

Median nerve, C8, T1 (see Fig. 1-29). See Appendix F.

#### Action

1. Palmar abduction of the thumb (perpendicular to the plane of the palm).
2. Assistance in opposition and in flexion of the proximal phalanx of the thumb.

#### Test

Palmar abduction of the thumb is tested against resistance applied at the metacarpophalangeal joint.

The muscle is readily visible and palpable in the thenar eminence.

#### Participating Muscle

Flexor pollicis brevis (superficial head).

#### Opponens Pollicis (see Fig. 1-40)

Median nerve, C8, T1 (see Fig. 1-29). See Appendix F.

**Action**

Movement of the first metacarpal across the palm, rotating it into opposition.

**Test**

The thumb is in opposition. The examiner attempts to rotate and draw the thumb back to its usual position.

**Participating Muscles**

Abductor pollicis brevis; flexor pollicis brevis.

**Flexor Pollicis Brevis (Fig. 1-40)**

Superficial head (median nerve, C8, T1); deep head (ulnar nerve, C8, T1) (see Fig. 1-29). See Appendix F.

**Action**

1. Flexion of the proximal phalanx of the thumb.
2. Assistance in opposition, ulnar adduction (entire muscle), and palmar abduction (superficial head) of the thumb.

**Test**

1. The thumb is in the position of palmar adduction, with stabilization of the metacarpal.
2. Flexion of the proximal phalanx is tested against resistance applied to that phalanx, while the distal phalanx is as relaxed as possible.

**Participating Muscles**

Flexor pollicis longus; abductor pollicis brevis; adductor pollicis.

Severe median nerve palsy produces the “simian” hand, wherein the thumb tends to lie in the same plane as the palm, with the volar surface facing more anteriorly than normal. Atrophy of the muscles of the thenar eminence is usually conspicuous.

Three muscles supplied, at least in part, by the ulnar nerve have already been described: the flexor carpi ulnaris, the flexor digitorum profundus, and the flexor pollicis brevis. The remaining muscles supplied by this nerve are described below.

**Hypothenar Muscles (see Fig. 1-40)**

Ulnar nerve, C8, T1 (see Fig. 1-29). See Appendix G.

**Action**

1. Abductor digiti minimi and flexor digiti minimi: abduction and flexion (proximal phalanx) of the little finger.
2. Opponens digiti minimi: opposition of the little finger toward the thumb.
3. All three muscles: palmar elevation of the head of the fifth metacarpal, helping to cup the palm.

**Test**

The action usually tested is abduction of the little finger (against resistance).

The abductor digiti minimi is readily observed and palpated at the ulnar border of the palm. Opposition of the thumb and the little finger can be tested together by gauging the force required to separate the tips of the two digits when opposed or by attempting to withdraw a piece of paper clasped between the tips of the digits.

**Interossei (Figs. 1-41 and 1-42)**

Ulnar nerve, C8, T1 (see Fig. 1-29). See Appendix G.

**Action**

1. Dorsal: abduction of the index, middle, and ring fingers from the middle line of the middle finger (double action on the middle finger: both radial and ulnar abduction; radial abduction of the index finger; ulnar abduction of the ring finger).
2. First dorsal: adduction (especially palmar adduction) of the thumb.
3. Palmar: adduction of the index, ring, and little fingers toward the middle finger.
4. Both sets: flexion of metacarpophalangeal joints and simultaneous extension of the interphalangeal joints.

**Test**

1. Abduction and adduction of the individual fingers are tested against resistance, with the fingers extended. Adduction can be tested by retention of a slip of paper between the fingers and between the thumb and the index finger, as the examiner attempts to withdraw it.
2. Ability of the patient to flex the proximal phalanges and simultaneously extend the distal phalanges.
3. Extension of the middle phalanges of the fingers against resistance while the examiner stabilizes the proximal phalanges in hyperextension.

The long extensors of the fingers (radial nerve) and the lumbrical muscles (median and ulnar nerves) assist in extension of the middle and distal phalanges. The first dorsal interosseous is readily observed and palpated in the space between the index finger and the thumb.

**Adductor Pollicis (see Fig. 1-42)**

Ulnar nerve, C8, T1 (see Fig. 1-29). See Appendix G.

**Action**

Adduction of the thumb in both the ulnar and the palmar directions (in the plane of the palm and perpendicular to the palm, respectively). Assistance in flexion of the proximal phalanx.

**Test**

Adduction in each plane is tested against resistance by retention of a slip of paper between the thumb and the radial border of the hand and between the thumb and the palm, without flexion of the distal phalanx.

**FIGURE 1-41.** Dorsal view of the chief abductors of the digits. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:212. Used with permission of Mayo Foundation for Medical Education and Research.)

**FIGURE 1-42.** The chief adductors of the digits. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:213. Used with permission of Mayo Foundation for Medical Education and Research.)

It is often possible to palpate the edge of the adductor pollicis just volar to the proximal part of the first dorsal interosseous.

### Participating Muscles

1. Ulnar adduction: first dorsal interosseous; flexor pollicis longus; extensor pollicis longus; flexor pollicis brevis.
2. Palmar adduction: first dorsal interosseous, in particular; extensor pollicis longus.

### Flexors of the Neck

Cervical nerves, C1-6.

#### Test

Sitting or supine: flexion of the neck, with the chin on the chest, is tested against resistance applied to the forehead.

### Extensors of the Neck

Cervical nerves, C1-T1.

#### Test

Sitting or prone: extension of the neck is tested against resistance applied to the occiput.

### Diaphragm

Phrenic nerves, C3-5.

#### Action

Abdominal respiration (inspiration) is distinguished from thoracic respiration (expiration), which is produced principally by the intercostal muscles.

#### Test

1. The patient is observed for protrusion of the upper portion of the abdomen during deep inspiration when the thoracic cage is splinted.
2. The patient is observed for ability to sniff.
3. Litten phenomenon (successive retraction of the lower intercostal spaces during inspiration) may be observed if the patient's body habitus permits, such as in thin individuals.
4. Diaphragmatic movements are observed fluoroscopically. Unilateral phrenic nerve palsy leads to diaphragmatic movement on one side but not the other (Litten sign).

Weakness of the diaphragm should be suspected in disease of the spinal cord when the deltoid or biceps is paralyzed, because these muscles are supplied by neurons situated close to those that innervate the diaphragm.

### Intercostal Muscles

Intercostal nerves, T1-11.

#### Action

Expansion of the thorax anteroposteriorly and transversely, producing thoracic inspiration.

#### Test

1. Observation and palpation of the expansion of the thoracic cage during deep inspiration while maintaining pressure against the thorax.
2. Observation for asymmetric movement of the thorax, particularly during deep inspiration.
3. Other more general tests of function of the respiratory muscles are as follows:
  - (a) Observation of the patient for rapid shallow respiration, flaring of ala nasi, and the use of accessory muscles of respiration.
  - (b) Ability of the patient to repeat three or four numbers without pausing for breath.
  - (c) Ability of the patient to hold his or her breath for 15 seconds.

### Anterior Abdominal Muscles

Upper (T6-9); lower (T10-L1).

#### Test

1. Supine: flexion of the neck is tested against resistance applied to the forehead by the examiner. Contraction of the abdominal muscles can be observed and palpated. Upward movement of the umbilicus is associated with weakness of the lower abdominal muscles (Bevor sign).
2. Supine: hands on the occiput. Flexion of the trunk by anterior abdominal muscles is followed by flexion of the pelvis on the thighs by the hip flexors (chiefly iliopsoas) to reach a sitting position. The examiner holds down the patient's legs.

Completion of this test can exclude significant weakness of either the abdominal muscles or the flexors of the hips. Weak abdominal muscles, in the presence of strong hip flexors, result in hyperextension of the lumbar spine during attempts to elevate the legs or to rise to a sitting position.

### Extensors of the Back

See Figure 1-43.

#### Test

Prone: with the hands clasped over the buttocks, the patient elevates his or her head and shoulders off the table while the examiner holds down the patient's legs.

The gluteal and hamstring muscles fix the pelvis on the thigh.

### Iliopsoas (Fig. 1-44)

Psoas major (lumbar plexus, L2-4); iliacus (femoral nerve, L2-4). See Appendix H.

#### Action

Flexion of the thigh at the hip.

#### Test

1. Sitting: flexion of the thigh is tested by raising a knee against resistance by the examiner.

**FIGURE 1-43.** The chief muscles of the back. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:236. Used with permission of Mayo Foundation for Medical Education and Research.)

2. Supine: flexion of the thigh is tested by raising an extended leg off the table and maintaining it against downward pressure applied by the examiner just above the knee.

### Participating Muscles

Rectus femoris and sartorius (both: femoral nerve, L2-4); tensor fasciae latae (superior gluteal nerve, L4, L5).

### Adductor Magnus, Longus, Brevis (see Fig. 1-44)

Obturator nerve, L2-4; part of adductor magnus is supplied by sciatic nerve, L5, and functions with hamstrings. See Appendix I.

### Action

Adduction of the thigh principally.

### Test

Sitting or supine: the knees are held together while the examiner attempts to separate them.

The legs also can be tested separately and the muscles palpated.

**FIGURE 1-44.** The superficial muscles of the anterior aspect of the thigh. (Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:281. Used with permission of Mayo Foundation for Medical Education and Research.)

### Participating Muscles

Gluteus maximus; gracilis (obturator nerve, L2-4).

### Abductors of the Thigh (Fig. 1-45)

Superior gluteal nerve, L4, L5, S1.

1. Gluteus medius and gluteus minimus principally.
2. Tensor fasciae latae to a lesser extent.

### Action

1. Abduction and medial rotation of the thigh.
2. Tensor fasciae latae assists in flexion of the thigh at the hip.

**FIGURE 1-45.** The abductors of the thigh. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:315. Used with permission of Mayo Foundation for Medical Education and Research.)

#### Test

1. Sitting: the knees are separated against resistance by the examiner. In this position, the gluteus maximus and some of the other lateral rotators of the thigh function as abductors, hence diminishing the accuracy of the test.
2. Supine: same test as for abductors, above, but more exact.
3. Lying on opposite side: the hip is abducted (moved upward) while the examiner presses downward on the lower leg and stabilizes the pelvis.

**FIGURE 1-46.** The musculature of the gluteal region. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:300. Used with permission of Mayo Foundation for Medical Education and Research.)

The tensor fasciae latae and, to a lesser extent, the gluteus medius can be palpated.

#### Medial Rotators of the Thigh (see Fig. 1-45)

Same as abductors; superior gluteal nerve, L4, L5, S1.

#### Test

Sitting or supine: the knee is flexed to 90 degrees. Medial rotation of the thigh is tested against resistance applied by the examiner at the knee and the ankle in an attempt to rotate the thigh laterally.

#### Lateral Rotators of the Thigh (Fig. 1-46)

L4, L5, S1, S2.

1. Gluteus maximus (inferior gluteal nerve, L5, S1, S2) chiefly.
2. Obturator internus and gemellus superior (nerve to obturator internus, L5, S1, S2).
3. Quadratus femoris and gemellus inferior (nerve to quadratus femoris, L4, L5, S1).

#### Test

Sitting or supine: the knee is flexed to 90 degrees. Lateral rotation of the thigh is tested against an attempt by the examiner to rotate the thigh medially.

The gluteus maximus is the muscle principally tested, and it can be observed and palpated in the prone position.

#### Gluteus Maximus (see Fig. 1-46)

Inferior gluteal nerve, L5, S1, S2.

#### Action

1. Extension of the thigh at the hip.
2. Lateral rotation of the thigh.
3. Assistance in adduction of the thigh.

**FIGURE 1-47.** Flexors of the thigh. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:317. Used with permission of Mayo Foundation for Medical Education and Research.)

### Test

1. Sitting or supine: starting with the thigh slightly raised, extension (downward movement) of the thigh is tested against resistance applied by the examiner under the distal part of the thigh. In this rather crude test, the muscle cannot be observed or readily palpated.
2. Prone: the knee is well flexed to minimize the participation of the hamstrings. Extension of the thigh is tested by raising the knee from the table against downward pressure applied by the examiner to the distal part of the thigh. The muscle is accessible to observation and palpation in this position.

### Quadriceps Femoris (Fig. 1-47)

Femoral nerve, L2-4. See Appendix H.

### Action

1. Extension of the leg at the knee.
2. Rectus femoris assists in flexion of the thigh at the hip.

### Test

1. Sitting or supine: the lower leg is in moderate extension.
2. Maintenance of extension is tested against effort by the examiner to flex the patient's leg at the knee.

Atrophy is easily noted.

**FIGURE 1-48.** The flexors of the leg. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:320. Used with permission of Mayo Foundation for Medical Education and Research.)

### Hamstrings (Fig. 1-48)

Sciatic nerve, L4, L5, S1, S2. See Appendix J. Biceps femoris: external hamstring (L5, S1, S2). Semitendinosus and semimembranosus: internal hamstrings (L4, L5, S1, S2).

### Action

1. Flexion of the leg at the knee.
2. All but the short head of the biceps femoris assist in extension of the thigh at the hip.

### Test

1. Sitting: flexion of the lower leg is tested against resistance.
2. Prone: the knee is partly flexed. Further flexion is tested against resistance.

Observation and palpation of the muscles and the tendons are important for proper interpretation.

### Anterior Tibialis (Figs. 1-49 and 1-50)

Deep peroneal nerve, L4, L5, S1. See Appendix K.

**FIGURE 1-49.** The lateral muscles of the leg. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:338. Used with permission of Mayo Foundation for Medical Education and Research.)

### Action

Dorsiflexion and inversion (particularly in the dorsiflexed position) of the foot.

### Test

Dorsiflexion of the foot is tested against resistance applied to the dorsum of the foot downward and toward eversion.

The belly of the muscle just lateral to the shin and the tendon medially on the dorsal aspect of the ankle should be observed and palpated to be certain that dorsiflexion is not being accomplished by the extensor digitorum longus without contraction of the anterior tibialis. Atrophy is conspicuous.

### Participating Muscles

1. Dorsiflexion: extensor hallucis longus; extensor digitorum longus.
2. Inversion: posterior tibialis.

**FIGURE 1-50.** The dorsiflexors of the foot. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:345. Used with permission of Mayo Foundation for Medical Education and Research.)

### Extensor Hallucis Longus (see Figs. 1-49 and 1-50)

Deep peroneal nerve, L5, S1. See Appendix K.

### Action

Extension of the great toe and dorsiflexion of the foot.

### Test

Extension of the great toe is tested against resistance, while the foot is stabilized in a neutral position.

The tendon is palpable between the tendons of the anterior tibialis and the extensor digitorum longus.

### Extensor Digitorum Longus (see Figs. 1-49 and 1-50)

Deep peroneal nerve, L4, L5, S1. See Appendix K.

### Action

Extension of the lateral four toes and dorsiflexion of the foot.

**Test**

Extension of the lateral four toes and dorsiflexion of the foot are tested against resistance.

The tendons are visible and palpable on the dorsal aspect of the ankle and the foot lateral to the tendon of the extensor hallucis longus.

**Extensor Digitorum Brevis (see Fig. 1-49)**

Deep peroneal nerve, L4, L5, S1. See Appendix K.

**Action**

Assists in the extension of all the toes except the little toe.

**Test**

The belly of the muscle is observed and palpated on the lateral aspect of the dorsum of the foot during toe extension.

**Peroneus Longus, Brevis (Fibularis Longus, Brevis) (Fig. 1-51)**

Superficial peroneal nerve, L5, S1. See Appendix L.

**Action**

1. Eversion of the foot.
2. Assistance in plantar flexion of the foot.

**FIGURE 1-51.** Evertors of the foot. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:346. Used with permission of Mayo Foundation for Medical Education and Research.)

**Test**

The foot is in plantar flexion. Eversion is tested against resistance applied by the examiner to the lateral border of the foot.

The tendons are palpable just above and behind the external malleolus. Atrophy may be visible over the anterolateral aspect of the lower extremity.

**Gastrocnemius; Soleus (Fig. 1-52)**

Tibial nerve, L5, S1, S2. See Appendix J.

**Action**

1. Plantar flexion of the foot.
2. The gastrocnemius also flexes the knee and cannot act effectively to plantar flex the foot when the knee is well flexed.

**Test**

1. The knee is extended to test both muscles. The knee is flexed principally to test the soleus.
2. Plantar flexion of the foot is tested against resistance.

**FIGURE 1-52.** Musculature of the calf of the leg. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:333. Used with permission of Mayo Foundation for Medical Education and Research.)

The muscles and tendon should be observed and palpated. Atrophy is readily visible. The gastrocnemius and soleus are strong muscles, and leverage in testing favors the patient rather than the examiner. For this reason, slight weakness is difficult to detect by resisting flexion of the ankle or by pressing against the flexed foot in the direction of extension. Consequently, the strength of these muscles should be tested against the weight of the patient's body. The patient should stand on one foot and plantar flex the foot to lift himself or herself directly and fully upward. It may be necessary for the examiner to hold the patient steady while this test is performed.

### Participating Muscles

Long flexors of the toes; posterior tibialis, fibularis longus, and fibularis brevis (particularly near the extreme plantar flexion).

### Posterior Tibialis (Fig. 1-53)

Posterior tibial nerve, L5, S1. See Appendix J.

### Action

1. Inversion of the foot.
2. Assistance in plantar flexion of the foot.

**FIGURE 1-53.** Invertors of the foot. (From Jenkins DB. *Hollinshead's Functional Anatomy of the Limbs and Back*. 8th ed. Philadelphia, PA: WB Saunders; 2002:345. Used with permission of Mayo Foundation for Medical Education and Research.)

### Test

The foot is in complete plantar flexion. Inversion is tested against resistance applied to the medial border of the foot and directed toward eversion and slightly toward dorsiflexion.

This maneuver virtually eliminates participation of the anterior tibialis in inversion. The toes should be relaxed to prevent participation of the long flexors of the toes.

### Long Flexors of the Toes (see Fig. 1-53)

Posterior tibial nerve, L5, S1. See Appendix J.

1. Flexor digitorum longus.
2. Flexor hallucis longus.

### Action

1. Plantar flexion of the toes, especially at the distal interphalangeal joints.
2. Assistance in plantar flexion and inversion of the foot.

### Test

1. The foot is stabilized in a neutral position. Plantar flexion of the toes is tested against resistance applied to the distal phalanges.
2. Weakness of the long toe flexors results in inability to curl the tips of the toes under the foot against resistance. (See intrinsic foot muscle testing below.)

### Intrinsic Muscles of the Foot

Virtually all muscles except the extensor digitorum brevis (medial and lateral plantar nerves from the posterior tibial nerve, L5, S1, S2).

### Action

The flexion of the proximal phalanges during extension of the distal phalanges is an action comparable to that of the intrinsic muscles of the hand.

### Test

The patient's foot is stabilized in a neutral position, and plantar flexion of the toes is tested against resistance applied to the distal phalanges. (Same maneuver as that in the test of the long toe flexors.)

### Neurologic Examination

With the exception of the musculoskeletal examination, no other component of the standard physical examination is more important to the physical medicine and rehabilitation assessment than the neurologic examination. Although often conducted to identify disease, the neurologic examination provides the physiatrist with an opportunity to identify both the neurologic impairments to be addressed and the residual abilities to be used in maximizing the functional outcome for the patient.

Although it is customary to record the results of the neurologic examination in a separate portion of the examination report, the neurologic examination is rarely performed all at one time. The examiner often finds it convenient to integrate the appropriate

portions of the neurologic examination into the assessment of a specific region of the body. For example, cranial nerve assessment often is performed with other components of the head and neck examination, because the patient is positioned appropriately for both. For purposes of discussion, the neurologic examination is addressed separately and is divided into assessments of mental status, speech and language function, cranial nerves, reflexes, central motor integration, sensation, and perception. Muscle strength is discussed in the section on examination of the musculoskeletal system. The assessment of complex motor activities is discussed in the section “Functional Examination.” The reader is referred to *Mayo Clinic Examinations in Neurology* for a comprehensive discussion of the neurologic evaluation (1).

## Mental Status

### Level of Consciousness

Before performing a formal mental status examination, the examiner should determine the patient's level of consciousness. Qualitative terms such as “drowsy,” “lethargic,” and “stuporous” are useful in a descriptive sense, but they suffer from a lack of precise definition. “Stuporous” to one examiner may mean “lethargic” to another. A definitive classification of mental status requires a standardized approach (13–15). In the Glasgow Coma Scale, the examiner classifies the patient's eye, motor, and verbal responses to verbal and physical stimuli according to a numerical scale that is quantifiable and reproducible (Table 1-4) (16). Such a standardized scale is necessary to assess changes over time and to facilitate communication among physicians, nurses, therapists, and family members. In

patients with traumatic brain injury, other aspects of the neurologic assessment, such as pupillary responses, ocular movements, and respiration, will provide information about the cause of altered consciousness but do not quantifiably relate in a statistical sense to eventual outcome.

### Cognitive Evaluation

With the conscious patient, assessment of mental status begins when the physician enters the room and continues throughout the examination. However, as with the assessment of the level of consciousness, a formal approach to the mental status examination can help the examiner to identify and quantify specific impairments and residual capacity, to recognize subtle temporal changes, and to facilitate communication among caregivers. A commonly used clinical tool for evaluating the patient's mental status is the Folstein Mini-Mental Status Examination (13). Excellent systems have been developed to assess intellectual performance in specific populations (10,16). Although systems may or may not include perceptual testing, speech and language assessment, or an inventory of thought processing, certain components of the evaluation remain constant.

### Orientation

The patient is asked to report his or her name, address, and telephone number and the building (e.g., hospital or clinic), city, state, year, month, and day.

### Attention

Attention is assessed with digit repetition; the patient is asked to repeat a series of random numbers. Two numbers are used initially (e.g., 4 and 9); if the patient answers correctly, the sequence is increased by one more digit with each additional repetition until the patient either repeats seven digits correctly or makes a mistake. The number of digits repeated correctly should be noted.

### Recall

Three numbers or three objects are listed, and the patient is asked to remember them for repetition later. In 5 minutes, the patient is asked to recall the list, and the number of correct responses is recorded. If all responses are correct, recall responses are obtained again at 10 minutes and at 15 minutes.

### General Fund of Information

Questions are asked appropriate to the patient's age, cultural interests, and educational background. For example, the names of the past five US presidents or leaders of other countries, the current US vice president, and the governor of the patient's home state can be requested, or inquiries can be made for information about current events and other nearly universal subjects (e.g., world wars and basic scientific principles).

### Calculations

The patient is asked to count by sevens, and the last correct response is recorded. Arithmetic calculations of increasing difficulty are presented.

**TABLE 1.4** Glasgow Coma Scale<sup>a</sup>

Response	Score
Eye opening, E	
Spontaneous	E 4
To speech	E 3
To pain	E 2
Nil	E 1
Best motor response, M	
Obeys	M 6
Localizes	M 5
Withdraws	M 4
Abnormal flexion	M 3
Extensor response	M 2
Nil	M 1
Verbal response, V	
Orientated	V 5
Confused conversation	V 4
Inappropriate words	V 3
Incomprehensible sounds	V 2
Nil	V 1

<sup>a</sup>Goma score (E + M + V) = 3 to 15.

From Jennett B, Teasdale G, eds. *Management of Head Injuries*. Philadelphia, PA: FA Davis Company; 1981, used with permission.

### ***Proverbs***

An explanation of three common proverbs is requested. The patient is assessed as to whether he or she can abstract the principle from the adage and explain it in concrete terms.

### ***Similarities***

The patient is asked to describe what is common to an orange and an apple, to a desk and a bookcase, and to a cup and a fork. The number of correct responses is recorded.

### ***Judgment***

The patient is presented with three problems (e.g., smelling smoke in a movie theater, finding a stamped and addressed envelope on the sidewalk, and locating a friend in an unfamiliar city) and asked how to handle each situation.

## **Speech and Language Function**

As with the assessment of mental status, the analysis of communicative function occurs throughout the entire examination. The patient should be evaluated for the presence and extent of aphasia, apraxia, and dysarthria and for any residual communicative skills (17,18). At times, effort is required to discriminate among the disorders of aphasia, apraxia of speech, and language dysfunction associated with a more generalized cognitive deficit. Expert assessment of speech production and language processing can be valuable for diagnosis of neurologic disease (see Chapter 15). However, as described in the preceding section, assessment of the four basic elements of communication (i.e., listening, reading, speaking, and writing) provides a practical framework for functional evaluation.

### ***Listening***

After first determining that the patient does not have a significant hearing loss, had been able to speak the examiner's language before the onset of disease, and has the requisite motor and visual skills, the physician should test the patient's auditory comprehension, noting the extent of his or her ability to follow specific directions without gestures from the examiner. Often, it is useful to characterize the degree of impairment with stepped commands. First, the patient's ability to follow one-step commands is assessed by asking him or her to perform three different single motor activities, such as "take off your glasses," "touch your nose," and "open the book." Each command should be given separately, and a prolonged pause should be allowed to observe the response. These responses are rated and notation is made of whether the patient requires pantomime of the activity before performing the task. If two of the three responses are correct, an assessment should be made of the patient's skill at following two-step commands, such as "touch your nose, then take off your glasses," "point to the window, then close the book," and "touch my hand, then touch your knee." If the patient can follow two-step commands, then an assessment of his or her ability to follow three-step commands is conducted in a similar fashion. A simple object such as a toothbrush is held up,

and the patient is asked to demonstrate its use. This request is repeated at least two more times with different objects. If speech is functional, the patient is asked to repeat a short phrase that is spoken. The response should be observed for perseveration and jargon.

### ***Reading***

It is important to verify that the patient had reading skills before the onset of the neurologic disorder. The patient should be asked to read a short written command and perform the activity; the patient also can be asked to follow written two-step and three-step commands. If writing is otherwise functional, the patient should be asked to read aloud what he or she has written.

### ***Speaking***

If auditory comprehension is adequate, language production can be tested in several ways. An object is indicated, and the patient is asked to name it and state its function; at least three objects are used. The patient is asked to report his or her name, hometown, telephone number, or another simple verifiable fact. A picture can be shown and the patient asked to describe it. Tests for phonation and resonance deficits are performed by asking the patient to say a prolonged "aaah" and by observing for force and steadiness of pitch and tone. The patient should be asked to say "pa-pa-pa" to test lip closure, "ta-ta-ta" to test tongue function, and "ka-ka-ka" to test speed, regulatory, and posterior pharyngeal function. If reading is otherwise functional, articulation can be further assessed by having the patient read aloud a short passage containing various vowels and consonants.

### ***Writing***

The patient should be asked to write his or her name, address, telephone number, and a brief paragraph.

## **Cranial Nerves**

### ***Cranial Nerve I (Olfactory)***

Olfactory function should be evaluated routinely. Deficits are common after head trauma.

### ***Cranial Nerve II (Optic)***

Visual field testing of each eye should be performed, with a temporary patch over the contralateral eye. It is best to test each quadrant diagonally to identify any quadrantanopia. Although visual double simultaneous stimulation may be more correctly classified under cortical sensation, it is convenient to assess for extinction during visual field testing, after full fields have been verified. Visual acuity is discussed in the section on "Eye Examination."

### ***Cranial Nerves III (Oculomotor), IV (Trochlear), and VI (Abducens)***

Visual pathways are assessed by evaluating the pupil size, pupillary reactions, and extraocular movements. Strabismus is evaluated by testing corneal light reflections.

***Cranial Nerve V (Trigeminal)***

The muscles of mastication and facial sensation should be tested.

***Cranial Nerve VIII (Vestibulocochlear)***

The patient should be examined for nystagmus. Auditory function is discussed in the section on “Ear Examination.”

***Cranial Nerves VII (Facial), IX (Glossopharyngeal), X (Vagus), and XII (Hypoglossal)***

Isolating individual cranial nerve function emanating from the lower part of the brainstem is difficult. Cranial nerves are often grouped by function. Evaluation should be conducted of taste (nerves VII, IX, and X), muscles of facial expression (nerve VII) and articulation (nerves VII, IX, X, and XII), and swallowing function (nerves IX, X, and XII).

***Cranial Nerve XI (Accessory)***

The function of sternocleidomastoid and trapezius is frequently assessed during manual muscle testing.

Brainstem- and visual-evoked responses, electromyography and other forms of electrodiagnostic testing, and swallowing videofluoroscopy are often necessary for better delineation of dysfunction of cranial nerves and their brainstem interactions.

**Reflexes*****Muscle Stretch Reflexes***

Muscle stretch reflexes should be tested when the patient is relaxed. The commonly tested muscles are the biceps (C5, C6), triceps (C6-8), brachioradialis (C5, C6), quadriceps (L2-4), and gastrocnemius-soleus (L5, S1, S2). The reflexes of the masseter (cranial nerve V), internal hamstring (L4, L5, S1, S2), and external hamstring (L5, S1, S2) are tested in select cases. The patient should be observed for clonus.

***Superficial Reflexes***

Segmental reflexes are often helpful for localizing the lesion. These include the corneal (cranial nerves V and VII), gag (cranial nerves IX and X), anal (S3-5), and plantar (L5, S1, S2) reflexes. At times, it is useful to include the epigastric (T6-9), midabdominal (T9-11), hypogastric (T11, T12, L1), and cremasteric (L1, L2) reflexes.

***Pathologic Reflexes***

Elicitation of the Babinski reflex should be attempted. In questionable cases, the confirmatory Chaddock, Oppenheim, and Stransky reflexes should be tested.

**Central Motor Integration*****Muscle Tone***

Spasticity, rigidity, and hypotonicity can be assessed by evaluating the patient's resistance to passive movement, pendulousness, and ability to posturally fixate.

***Coordination***

Coordination in the upper extremities can be assessed with the finger-nose, finger-nose-finger, and knee-pat tests. Coordination in the lower extremities can be evaluated with the toe-finger and heel-knee-shin test.

***Alternate Motion Rate***

The tongue-wiggle, finger-wiggle, and foot-pat tests can be used to identify subtle spasticity, rigidity, and incoordination.

***Involuntary Movements***

The patient should be observed for tremors, chorea, athetosis, ballismus, dystonia, myoclonus, asterixis, and tics. If present, these should be described in the neurologic report.

***Apraxia***

Apraxia is the failure of motor planning and execution without deficits in strength, coordination, or sensation; however, deficits of strength, coordination, and sensation are often also present because of the extent of the lesion. Automatic motor activities can be observed while the patient manipulates a pen or pencil, handles clothing, and moves about the examination room; then, the patient's ability to perform some of the same maneuvers on command can be assessed. The patient should be asked to touch his or her nose, drink from a glass, put a pencil in the glass, and use scissors. The patient should then be asked to perform these activities without the objects with each hand. Inefficient or fumbling movements or inability to accomplish the task should be noted. Dressing apraxia can be assessed by asking the patient to put on a coat. To assess for more subtle deficits, the examiner should first turn one sleeve of the coat inside out. Constructional apraxia can be evaluated by asking the patient to copy a geometric design or draw the face of a clock.

**Sensation*****Superficial Sensation***

Light touch can be tested with a wisp of cotton, superficial pain with a single-use pin, and temperature with two test tubes, one with hot tap water and the other with cold tap water. Abnormal findings should be recorded on a drawing of the human figure and compared with standard charts of spinal dermatomes and peripheral nerves (1).

***Deep Sensation***

The evaluation of joint position sense begins with the distal joints of the hand and foot and moves proximally until normal sensation is identified. Testing for deep pain in the upper extremities can be done by hyperextension of small finger joints and in the lower extremities by firm compression of the calf muscles or Achilles tendon. Vibration sense is often evaluated, but its isolated absence does not result in functional deficit.

***Cortical Sensation***

If superficial and deep sensations are intact, two-point discrimination, graphesthesia, stereognosis, and double simultaneous stimulation can be evaluated.

## Perception

Disorders of perception are most common with lesions of the nondominant parietal lobe but also can occur with lesions on the dominant side.

### *Agnosia*

Agnosia is the failure to recognize familiar objects despite intact vision, hearing, sensation, and language function (although language is also often deficient because of the extent of the lesion). Pictures of common objects or the objects themselves are shown, and the patient is asked to identify them and describe their components. Agnosia of body parts can be assessed by asking the patient to identify his or her (or the examiner's) arm, finger, or eye. Unilateral environmental neglect can be assessed by observing ambulation or wheelchair operation for difficulty clearing corners and doorjamb, extinction on double simultaneous stimulation, and failure to scan the complete page width when asked to read a passage or cross out all the occurrences of the letter E. Body scheme agnosias can be evaluated by searching for denial of obvious physical impairments when the patient is asked to describe them.

### *Right-Left Disorientation*

If agnosia of body parts is not present, the patient should be asked to indicate various body parts on the right and the left sides.

### *Other Perceptual Tests*

If perceptual deficits are identified with the maneuvers described above, the examiner should test for additional deficits, such as impaired geographic and spatial orientation and figure-ground relationships. Comprehensive, formal, and quantitative testing of perception by a psychologist and an occupational therapist is warranted if any deficits are found during the physical examination.

## Functional Examination

After impairments have been identified, the consequences of each impairment for the function of the patient must be appraised. Prediction of functional status should not be attempted from the history and physical examination; instead, function should be examined. For a comprehensive assessment, the patient must be evaluated by individual physical medicine and rehabilitation team members in settings where the activities are actually performed. Bathing skills should be observed by the occupational therapist or the rehabilitation nurse in the bathroom while the patient attempts to bathe; eating skills should be analyzed by the occupational therapist while the patient eats a meal; and car transfer skills should be assessed by the physical therapist with the use of the patient's car. Each team member will use unique skills to contribute to a comprehensive determination of functional status. Many functional evaluative processes cannot be accomplished at a single point. Safety and judgment can be assessed only by observing

the patient in varying situations within both the rehabilitation environment and the community.

However, in many instances, the physiatrist must glean a basic view of the functional status at the time of the initial evaluation. For instance, in the clinic, the physician may be consulted to determine a patient's need for rehabilitation services. It is unlikely that the physician will be able to observe the patient during a meal, in the bathroom, or in the process of transferring to and from a car. In such cases, the physician must use creativity to place the patient in situations similar to those of daily life. Examples are given below. Components of the communication assessment were discussed in the sections "History and Physical Examination" and will not be repeated here.

### **Eating**

The patient should be asked to use examining equipment in place of feeding utensils to demonstrate proficiency in bringing food to the mouth. If aspiration has not already been identified, the patient should be provided with a glass of water and asked to drink.

### **Grooming**

The patient should be asked to comb his or her hair and to mimic the activities of brushing teeth or putting on makeup.

### **Bathing**

The patient should be asked to mimic the activities of bathing. It is important to note if any body parts cannot be reached by the patient, particularly the back, the scalp, and the axilla and arm contralateral to hemiparesis.

### **Toileting**

The patient must have adequate unsupported sitting balance, must have the requisite wrist and hand motion to reach the perineum adequately, must be able to handle toilet paper, and must be able to rise from low seating.

### **Dressing**

The patient should be observed during undressing before the examination and dressing after completion of the examination. The examiner should explain the purpose of the observation and should be accompanied by a nurse or aide.

### **Bed Activities**

During the physical examination, the examiner should note whether the patient has difficulty moving between the seated and the supine positions. It should also be determined whether the patient can roll from front to back and back to front and whether the patient can raise the pelvis off the examining table while supine.

### **Transfers**

The patient should be observed rising from seating with and without armrests and moving between the bed and a chair.

**TABLE 1.5** Gait Analysis*Standing balance*

Observe for steadiness of position; push the patient off balance and note the patient's attempts to regain balanced posture

*Individual body part movements during walking*

Observe for fixed or abnormal posture and inadequate, excessive, or asymmetrical movement of body parts

Head and trunk: listing or tilting, shoulder dipping, elevation, depression, protraction, and retraction

Arm swing: protecting positioning or posturing

Pelvis and hip: hip hiking, dropping (Trendelenburg), or lateral thrust

Knee: genu valgum, varum, or recurvatum

Foot and ankle: excessive inversion or eversion

*Gait cycle factors*

Cadence: rate, symmetry, fluidity, and consistency

Stride width: narrow or broad based; knee and ankle clearance

Stride length: shortened, lengthened, or asymmetrical

Stance phase: initial contact, loading response, toe off; knee stability during all components of stance; coordination of knee and ankle movements

Swing phase: adequate and synchronized knee flexion and ankle dorsiflexion during swing, abduction, or circumduction

**Wheelchair Mobility**

The patient should be asked to demonstrate wheeling straight ahead and turning, on both carpeted and noncarpeted floors, if available; locking the brakes; and manipulating the leg rests.

**Ambulation**

To adequately recognize disturbances of gait, the examiner must be able to view body parts. If the examining room is secluded, the assessment can be performed with the patient wearing only the underwear. If privacy is not possible, the patient should have

FUNCTIONAL STATUS

**FIGURE 1-54.** Sample of a functional status record.

access to washable or disposable shorts. If the examiner does not already have knowledge of the patient's ambulation skills, the patient should be provided with a safety belt before gait is assessed. To discern specific gait abnormalities, the examiner must study both the individual components and the composite activity. The patient should be observed from the front, back, and each side. If the patient experiences pain during ambulation, its temporal relationship to the gait cycle should be noted. This analysis must be approached in an orderly fashion. One routine for gait analysis is outlined in Table 1-5 (4,19). See Chapter 10 for a comprehensive discussion of gait.

### Operation of a Motor Vehicle

Driving ability can be assessed best in an automobile. However, the examiner can gain some information about the patient's motor abilities for driving by asking the patient to demonstrate the motions of operating the pedals and hand controls.

### Quantitation of Function

Several scales can be used to document and quantify functional status in activities of daily living. These are extremely useful in assessing a patient's rehabilitation progress (see Chapter 28). When validated and standardized, these scales are essential tools for analysis of rehabilitation outcome for

a series of patients participating in a specific intervention program. When they are used by multiple rehabilitation centers to share data, relevant information can be obtained to advance the field and to assess the cost versus the benefit of rehabilitation. Physicians should develop expertise in the use of these valuable tools.

However, the data collection for most validated functional scales requires additional time because they require interdisciplinary input; therefore, the initial documentation of functional status by the physician must be practical and complete. One such system is shown in Figure 1-54. Findings from both the history and the physical examination should be used to define functional status.

## SUMMARY AND PROBLEM LIST

After obtaining the history, performing the physical examination, and recording the results, the physiatrist should summarize the findings, construct a problem list, and formulate a plan.

A summary of findings can be a useful component of the written record. In a few sentences, a summary can provide a succinct description of relevant findings in the history and examination.

**TABLE 1.6** Example of Summary, Problem List, and Plan

#### Summary

A 55-year-old male carpenter with a left hearing deficit and poorly treated hypertension presents 4 d after sudden moderate left-side spastic hemiparesis with moderate sensory deficits, left neglect, nocturnal bladder incontinence, and dysarthria. He is alert, oriented, and normotensive; motor function in his left hip and knee is returning; and he has an elevated serum cholesterol level. He is divorced, lives alone, and has no close family. Computed tomography of the head shows moderate right subcortical infarction. Evidence of ischemia is not shown in the electrocardiogram.

#### Medical problems and plans

1. Right hemisphere infarction with motor, sensory, perceptual, and speech deficits: monitor neuromuscular function, maintain ROM, control spasticity (air splint, positioning, possible medications), provide motor reeducation, and provide patient education and risk factors
2. Hypertension: monitor systolic/diastolic blood pressure and treat with antihypertensive agents as appropriate
3. Dyslipidemia: low-fat diet, patient education about diet and food preparation, and lipid-lowering agents
4. Urinary incontinence: check residual urine volume and culture specimens; treat urosepsis. If residual volume is low, offer urinal frequently, with or without nocturnal condom catheterization. If residual volume is high, begin 1,800-mL fluid intake schedule with catheterization every 6 h, urodynamics, and bladder retraining

#### Rehabilitation problems and plans

1. Communication deficits: speech pathologist for evaluation and therapy
2. Left neglect: OT for perceptual testing, retraining, and compensation; verbal clues to scan left; RN and PT to reinforce OT
3. Left sensory deficits: monitor skin; offer patient education on care of insensate skin
4. Self-care deficits: OT for upper-extremity ROM, reeducation about strengthening, ADL retraining, adaptive aids
5. Safety and judgment deficits: four bed rails, RN monitoring at night, verbal clues, physical spotting
6. Transfer deficits: PT for retraining, left wheelchair brake extension
7. Mobility deficits: PT for lower-extremity ROM, reeducation about strengthening, gait retraining, gait aids
8. Driving dependency: retesting and retraining with improvement
9. Community reentry and poor support system: assess home for architectural barriers, assess home health services, identify additional social support
10. Reactive depression: refer for psychological support
11. Vocational issues: consider prevocational counseling and testing

ADL, activities of daily living; OT, occupational therapy; PT, physical therapy; RN, registered nurse; ROM, range of motion.

For the management of chronic diseases, physiatrists must commonly address myriad physical, psychological, social, and vocational problems. Weed's (20) problem-oriented medical record has been applied to the management of patients undergoing rehabilitation (21–24). Although the use of the problem list itself is the essential factor, a consensus as to the organization and the use of the entire system in the rehabilitation setting has proved challenging. The recommendation of Grabois (23) that medical and rehabilitation problems be separately listed is beneficial. In addition, it may be helpful to delineate individual plans for each problem at the conclusion of the workup (Table 1-6).

# The Physical Examination

The hallmark of medicine has always been the physical examination. Perhaps more than the actual diagnosis, the process by which the physician arrives at his or her conclusion has defined the “art” of medicine. Much has been written about the techniques by which this art is performed, and much more will continue to be written. Each generation will take from the past and apply these techniques to the future of medicine.

The physical examination is an extension of the history and extends the doctor-patient relationship initially established during the history. The skill with which the examination is performed instills a sense of confidence in the patient that the examiner knows what he or she is doing. This confidence in the physician has a positive outcome on the patient’s ability to recover. Finally, the physical examination serves to narrow the list of diagnostic possibilities.

In a specialty like physiatry, in which the whole person is evaluated in terms of function, there is no adjunct more important than the physical examination. The examination provides the foundation to formulate a plan to improve a person’s function. Importantly, though, in looking at function, each piece must be applied to the whole person. The examination of one joint must be applied to the whole picture of the patient, and an understanding of functional biomechanics will enable the physician to include in the physical examination other structures that may indirectly contribute to the impairment.

The focus on function and application to the whole person in physiatry can be best seen in understanding the concept of the kinetic chain. No one joint, bone, or muscle acts alone in the body. An ankle sprain can lead to low-back pain. Low-back pain can affect the serve of a tennis professional. Lateral epicondylitis can alter shoulder mechanics and lead to rotator cuff impingement. It is because of these relationships that the physiatrist must perform a thorough examination. It is this comprehensive manner that sets apart the physiatric approach from others. A thorough knowledge of the neuromuscular system and an understanding of functional biomechanics will narrow the focus of the examination so it can be done in a time-efficient manner. The relationship between the different joints and regions must be understood. In addition, a complete understanding of the muscles and their innervation is required.

An understanding of the muscle kinesiology and biomechanics is very important in the physical examination. Each muscle functions across one or more joints to provide motion

or stabilization. One example would be the hamstrings. When the foot is planted, the hamstrings act in their primary function as powerful hip extensors. However, with the foot off the ground, they can become knee flexors. With a patient prone and the knee bent at 90 degrees, the gluteus maximus acts as the primary extensor because of the shortened hamstrings. Place the knee in full extension, and the hamstrings will once again act as hip extensors. We will look further into these types of relationships in the physical examination.

In today’s medicine, there exists a tremendous amount of information to digest. The number of articles indexed in MEDLINE has grown in size from 1,098,000 citations in 1970 to 11,761,000 in 2000. The modern physician must have an understanding of the body down to a microcellular level. In addition, access to modern tests like magnetic resonance imaging (MRI) is achieved by a greater number of patients. Any test has its limitations, and in the example of the MRI, these can be multiple false-positive findings (1). The MRI should be used to confirm not make a diagnosis. Many physician referrals are generated from a radiologist’s interpretation of a study, often without physical examination findings consistent with the results of the study. It is at this point that the well-trained physiatrist can be the link using evidence-based medicine as it applies to diagnosis, history, and physical examination.

Whole texts are dedicated to the physical exam. Due to the limits of one chapter, this will be an introduction to the physical examination and kinesiology of the cervical spine, shoulder, lumbar spine, and knee. That said, the reader should be able to approach any joint in the manner laid out here to aid in his or her diagnosis. Examination of any joint should be performed in a systematic approach. As the examination begins, the clinician should make sure that the area to be examined is properly exposed for evaluation and the patient appropriately draped. We have focused on the major joints seen in our practice—the cervical and lumbar regions of the spine, the shoulder, and the knee. Other joints will be addressed in chapters in this text. We will now address the physical examination, and the kinesiology of the muscles and joints will be explained. For reference, the dermatomes, myotomes, and sclerotomes are illustrated in Chapter 21.

It is the task of the physiatrist to perform a thorough physical examination to confirm his or her diagnosis derived from the history and additional information. It even is more important today, because of the additional tests modern technology has advanced, to understand physical examination maneuvers and their diagnostic relevance.

## EXAMINATION OF THE CERVICAL SPINE

### Inspection

Inspection of the neck begins upon meeting the patient. Look to see if the patient moves the shoulders when he or she turns the neck, a sign of decreased range of motion, or if he or she winces with certain motions. Take note of the patient's relaxed posture as changes to improve poor posture can be easily addressed in therapy. As the examination proceeds, the clinician should make sure that the neck is properly exposed for evaluation. Look at the muscle bulk and symmetry of the neck, upper back, and shoulders. Also look at the skin for scarring or discoloration. You will be surprised at the details left out by patients. It is not uncommon to learn about a patient's previous surgery during the exam.

### Palpation

The next step involves palpation of the neck and upper thoracic region. Begin in a systematic fashion, either starting from the front or back. From the back, the paraspinal muscles and the nuchal ligament can be palpated. Working down, the upper and middle trapezius muscles should also be palpated for tender or trigger points (2). Palpate for the spinous process of the seventh cervical vertebrae, which should be larger than the superior segments in a neutral position of the cervical spine.

Place the patient in the supine position with the patient's head near the end of the table. Sit with your stool directly behind the patient's head, and continue palpation. Rotate the patient's neck 45 degrees, palpate each zygapophyseal joint, and note whether the patient feels discomfort at a joint that is greater than the opposite corresponding zygapophyseal joint. From this position, the anterior muscles, most notably the sternocleidomastoid and more laterally the scalenes, can be palpated. Palpate the sternocleidomastoid muscle from its origin at the sternoclavicular joint to the insertion on the mastoid process. Rotate the neck from side to side to make the muscle more prominent if it is initially difficult to find. Look for symmetry and bulk.

### Range of Motion

Range of motion should be tested both actively and passively. Both are important in the evaluation of the neck. Guarding due to pain, muscle tightness, and muscle imbalances can reduce range of motion to one side during active testing, but the motion may often be full when tested passively. Osteophytes and zygapophyseal joint arthritis can also lead to fixed restrictions. This would be confirmed when the same loss of range of motion found actively is also demonstrated passively.

**TABLE 2.1** Manual Muscle Testing of the Cervical Spine<sup>a</sup>

Root	Muscle
C5/6	<b>Biceps</b> , deltoid, and rotator cuff muscles
C6/7	<b>Wrist extensors</b> and pronator teres
C7/8	<b>Triceps</b> and wrist flexors
C8/T1	<b>Finger flexors</b> and intrinsic muscles of the hand
C8/T1	Intrinsic muscles of the hand

<sup>a</sup>Primary innervating root and initial muscle tested are shown in bold.

**TABLE 2.2** Reflex Testing of the Cervical Spine

Root <sup>a</sup>	Reflex
C5	Biceps
C6	Pronator teres or brachioradialis
C7	Triceps

<sup>a</sup>Primary innervating root tested.

Range of motion should be checked in flexion, extension, rotation, and lateral or side bending. Motion is not divided equally between the vertebrae. Approximately 50% of flexion and extension come from the atlanto-occipital joint. At the atlanto-axial joint, approximately 50% of the rotation takes place (3).

Guidelines for normal motion are as follows: Normal flexion allows the patient to touch his chin to his chest, and extension allows the patient to look up at the ceiling. In normal rotation, the patient should be able to bring her chin over the acromion. Side bending done toward the ipsilateral shoulder should be approximately 45 degrees. Always begin with active range of motion, particularly in the injured patient. The patient may guard, and this will reduce the range. Forcing motion may make the patient uncomfortable and can injure a patient with zygapophyseal joint dysfunction (4).

### Neurological

Included in any examination of the neck is a full neurologic examination of the upper limbs. Radiculopathies can be very subtle, and all components of the examination, manual muscle testing, sensory examination, and reflexes must be addressed to find these subtle changes. The order to proceed is examiner dependent. Manual muscle testing should also be confirmed with additional muscles when subtleties exist, as the muscles of the upper limb have two or more levels of innervation. Table 2-1 shows what should be included in manual muscle testing.

Reflexes can be addressed next. Table 2-2 shows what should be included in reflex testing.

Finally, sensation can be tested for both pinprick (lateral spinothalamic tract) and light touch (dorsal columns). If there is a concern about carpal tunnel or double crush, two-point discrimination may be more sensitive (5). Table 2-3 shows what should be included in sensation testing.

Examination of the neck should also include a compression test or Spurling's maneuver (6) (Fig. 2-1). The test assesses the

**TABLE 2.3** Sensation Testing of the Cervical Spine

Root <sup>a</sup>	Sensory Area
C5	Lateral (radial) side of the antecubital fossa
C6	Thumb
C7	Middle finger
C8	Little finger
T1	Medial (ulnar) side of the antecubital fossa

<sup>a</sup>Primary innervating root tested.

**FIGURE 2-1.** Compression test or Spurling's maneuver.

mechanical neuroforaminal narrowing of the C4-5, C5-6, and C6-7 with ipsilateral oblique extension (7). The objective of the test is to compress an irritated nerve with the following motion: The neck is brought into slight extension and side bending followed by an axial compression. A positive result reproduces pain along a dermatome below the shoulder. Finally, as with the joints, it is always important to examine the adjacent joints. In the case of the cervical spine, a full examination of the shoulder should be performed to rule out underlying or contributing shoulder pathology.

## EXAMINATION OF THE SHOULDER

### Inspection

Inspection of the shoulder requires that the shoulder be exposed and the patient appropriately draped. The shoulder “joint” actually consists of four different joints: sternoclavicular, acromioclavicular, glenohumeral, and scapulothoracic. Three of the joints are true joints, while the scapulothoracic joint is not a true articulating joint lined with cartilage. It is important to visualize each of the joints. Begin by inspecting the normal bony prominences and muscle bulk. The most obvious changes can be seen in the acromioclavicular joint. Comparison to the other shoulder is essential.

### Palpation

Palpation can be done either from in front of the patient or from behind the patient. Begin by palpating from the sternoclavicular joint along the clavicle to the acromioclavicular joint. Palpate the coracoid process and the coracoclavicular ligament. Move laterally, and palpate the tendon of the long head of the biceps. Continue palpation medially to the lesser tuberosity and laterally to the greater tuberosity. Next, palpate the scapula along the acromion and medially along the spine of the scapula. Find the superior and inferior angles of the scapula.

The muscles should also be palpated for tender points and evaluation of their bulk. The supraspinatus, infraspinatus, and teres minor can be palpated by bringing the upper limb into extension at the shoulder and palpating anteriorly (3).

### Range of Motion

The motion of the joints should be observed. Watch the different joints and their symmetry of motion. This should be done from in front of and behind the patient.

The shoulder has the greatest range of motion of any joint. Subtle changes must be assessed and asymmetries noted during the physical examination. Active and passive motions should be assessed. To begin, check the patient's active range of motion. There are six directions of motion: abduction, adduction, extension, flexion, internal rotation, and external rotation. Active abduction should allow the patient to touch the dorsal surface of his hands with the arms straight above the head. Adduction will allow the patient to bring her arm into the plane of the torso. Each of these can be tested in conjunction with the testing for internal and external rotations or alone. Functional internal rotation can be demonstrated by having the patient touch his midback (Fig. 2-2). Record the level that the thumb touches, and repeat on the opposite side. Have the patient reach over the head and touch the upper back to test external rotation. As with internal rotation, record both sides. Finally, have the patient bring the straight upper limb forward to test flexion and backward to test extension.

The shoulder should then be checked for passive range of motion. The importance of checking the passive range can be seen in a patient with adhesive capsulitis. Although there may appear to be both internal and external rotations, the motion often comes from the scapular thoracic joint. By isolating the glenohumeral motion, both can be assessed, and there is increased reliability in the assessment of the glenohumeral motion (8).

Passive internal and external rotations can be tested by bringing the shoulder into 90 degrees of abduction while holding

**FIGURE 2-2.** Internal rotation determination during shoulder range of motion evaluation.

**FIGURE 2-3.** Stabilization of the scapula during shoulder range of motion evaluation.

the elbow to 90 degrees of flexion. Stabilizing the scapula with one hand to truly evaluate glenohumeral motion, internally and externally rotate the shoulder (Fig. 2-3). For some examiners, placing the patient in the supine position with a posteriorly directed force on the coracoid process might be easier and has been found to be reliable (9). Note the motion, compare it to the other side, and repeat with the scapula free to see the scapulohumeral motion. Table 2-4 shows the normal range of motion.

### Neurological

Motor testing of the shoulder should follow the examination of the range of motion. Each motion should be tested for strength. The major muscles used to move the shoulder are the deltoid, pectoralis major, latissimus dorsi, biceps, and triceps. In addition, there are smaller stabilizing muscles, including the rotator cuff muscles. Additionally, the scapular position and control are coordinated by the trapezius, levator scapulae, rhomboids, and serratus anterior. Test the major movers with one hand stabilizing the shoulder and the other providing resistance.

After testing the larger movers of the shoulder, it is important that the smaller stabilizers are addressed, as these are often involved in the pathology of the shoulder. The supraspinatus is tested with the upper limb abducted 90 degrees, internally rotated with the thumb down and in the plane of the scapula. Apply steady pressure while asking the patient to abduct the limb

**FIGURE 2-4.** Supraspinatus strength determination during shoulder evaluation.

(Fig. 2-4). Next, the external rotators can be assessed. Have the patient adduct the limb and flex the elbow at 90 degrees. The examiner stabilizes the elbow against the torso with one hand and places the other hand on the distal forearm. The patient then rotates the forearm away from the body against resistance.

Finally, the subscapularis should be assessed. This is the most difficult to check for subtle changes. The classically described maneuver is the “lift-off test.” This is done by the patient placing the dorsum of his hand on his back while the elbow is flexed at 90 degrees. The examiner then holds the hand off the back and instructs the patient to hold his hand in that position once the hand is released. If the patient is able to maintain the hand position, the subscapularis is intact. If the hand falls to the back, there is some deficiency in the muscle (Fig. 2-5).

**FIGURE 2-5.** Subscapularis strength determination during shoulder evaluation.

**TABLE 2.4** Normal Range of Motion of the Shoulder

Motion	Degrees
Flexion	180
Extension	45
Abduction	180
Adduction	45
Internal rotation	55
External rotation	45

Sensory testing of the shoulder should be done in conjunction with the neck. Of importance for the shoulder, the dermatome for the axillary nerve should be tested. This is a silver dollar–sized area over the deltoid on the lateral upper arm. This is especially important after dislocations, as the axillary nerve can be injured.

### Additional Tests

#### Impingement Tests

There are many tests for impingement of the rotator cuff muscles. We will address two of the more common tests. The first is the Hawkins' maneuver (10). With the arm abducted to 90 degrees, elbow flexed at 90 degrees, and the humerus in the plane of the scapula, the examiner stabilizes the scapula and internally rotates the shoulder (Fig. 2-6). Pain with this maneuver is caused by impingement of the greater tuberosity on the coracoacromial ligament.

The Neer's impingement sign is performed by stabilizing the scapula and slowly forward flexing the shoulder (11; Fig. 2-7). The elbow should be straight during the maneuver. The limb can be tested both internally rotated and neutral during testing.

#### Labral Tests

Another test of importance to the shoulder exam is the active compression test. The test is used to assess for anterior labral tears and acromioclavicular injuries. With the patient standing, the examiner stands on the affected side. The shoulder is brought into 90 degrees of abduction, 10 to 15 degrees of adduction, and internal rotation of the upper limb. The patient then resists a downward force by the examiner. At this point, the patient should either feel pain at the top of the shoulder (A–C joint pathology) or inside the shoulder (anterior labrum). The limb is then brought into full external rotation and the symptoms should be alleviated. Sensitivity and specificity are both excellent for the test (12).

**FIGURE 2-6.** Hawkins' maneuver to evaluate shoulder rotator cuff impingement.

**FIGURE 2-7.** Neer's impingement sign to evaluate shoulder rotator cuff impingement.

#### Stability Tests

Shoulder instability can be diagnosed with a variety of maneuvers and most likely more accurately using the results of two or more tests. The examiner can begin with the apprehension test. The patient is placed in a supine position with the upper limb to be examined next to the edge of the table. The shoulder is then abducted to 90 degrees, and the elbow is flexed. The examiner then externally rotates the shoulder (Fig. 2-8). A patient with a positive “apprehension sign” has discomfort and a feeling of apprehension in the shoulder as it is externally rotated past 90 degrees that is relieved when the examiner stabilizes the shoulder with a posteriorly directed force to the shoulder with his free hand. The second part of the examination is named the “relocation sign” (Fig. 2-9). Both parts of the examination check for anterior instability of the shoulder, although the relocation test adds specificity to the diagnosis.

**FIGURE 2-8.** Apprehension sign to evaluate anterior instability of the shoulder.

**FIGURE 2-9.** Relocation sign to evaluate anterior instability of the shoulder.

The next tests are the anterior and posterior drawer signs (13). With the patient in the same supine position, the examiner stabilizes the forearm and the humerus. Next, the examiner places her free hand on the glenohumeral joint. With the distal portion of the joint stabilized, the humerus is directed anteriorly and posteriorly (Fig. 2-10). The amount that the humeral head moves beyond the rim of the glenoid fossa is graded in Table 2-5. Similarly, this can be applied to the posterior movement.

The final piece of instability is the inferior drawer or “sulcus sign.” With the patient seated or standing, the examiner pulls down the upper limb. The examiner’s free hand is stabilizing the scapula. A positive “sulcus sign” is when an indentation in the skin is noticed between the acromion and the humeral head (14).

### Sports Biomechanics

Identifying the biomechanical flaws in a thrower that contribute to the development of bicipital tendonitis or a

III	Subluxation

superior labrum anterior posterior (SLAP) lesion, or the flaws in a runner that lead to patellofemoral pain, requires an understanding muscle kinesiology and joint biomechanics. This helps determine not only the factors that may have been causative but also those that may increase the risk of an injury, and if so identified, allow prevention. This can be especially valuable during preparticipation examinations (15). The focus of sports medicine continues to be treatment rather than prevention. One reason for this is the limited scientific data that clearly demonstrate the effectiveness of prevention programs based on preinjury evaluations. Intuitively we believe that restrictions in motion or certain strength deficits may predispose an athlete to an injury, and if we address them, we can lower the risk. But do we have the research to back this up?

Much of our understanding of muscle kinesiology comes from work done in labs using electromyography (EMG) to look at muscle firing patterns. One must be extremely cautious interpreting these studies. Although very general muscle firing patterns can be determined, some important technical factors are often overlooked. The relative activity of one muscle cannot be compared with another for several reasons. One is that the amplitude of a muscle’s EMG signal varies widely based on whether a muscle is contracting concentrically or eccentrically. During certain sports activities, there will usually be muscles undergoing both (usually agonists and antagonists) types of contractions simultaneously, and it may not always be readily evident which is doing which. For example, during the acceleration phase of throwing, the shoulder flexes forward, but the exact point at which the shoulder internally rotates is important in determining which of the rotator cuff muscles are contracting concentrically and which are contracting eccentrically. To be certain, one must also perform a video kinematic analysis.

Several other factors play an important role in comparing the EMG signal of different muscles. The amplitude of the EMG signal will vary based on the location of the electrode (in relation to the muscle’s motor point), the type of electrode (surface vs. intramuscular), and the degree of muscle fatigue. Furthermore, because one compares the EMG activity to activity during maximal voluntary contraction (MVC) of the same muscle, activity determined during MVC must be reliable and statistically reproducible. This issue is frequently not fully and adequately addressed.

Nevertheless, the information collected on muscle kinesiology has allowed us to better understand basic muscle mechanics. Understanding the major technical limitations will help prevent us from drawing erroneous conclusions.

### Biomechanics of the Overhead Athlete

The biomechanics of the overhead athlete have been extensively studied. The motion of throwing a baseball and serving a tennis ball overhead has similarly been broken into five phases: windup, early cocking, late cocking, acceleration, and follow-through. The stage of late cocking, during which the shoulder is abducted and externally rotated, may potentially be dangerous to the glenohumeral joint, where inherent instability may lead to anterior translation and load the labrum or capsule anteriorly. Symptoms of posterior impingement can also be elicited when there is excessive anterior/posterior translation compressing redundant scar tissue in the region of the posterior capsule. Kinesiological studies have demonstrated that all four muscles of the cuff are most active from the late cocking to acceleration phase (16–18). This is not surprising because the cuff is felt to be a dynamic stabilizer of the glenohumeral joint, and the position in late cocking puts the glenohumeral joint in a potentially unstable position. Studies have also demonstrated that the triceps begins to fire in late cocking and then in acceleration (16,17). This is probably to prevent hyperflexion of the elbow during late cocking and may also serve as a prestretch to create a plyometric type of contraction of the triceps during acceleration to propel the forearm, wrist, and hand along with either the racquet or the baseball. The biceps then fires during the deceleration phase to allow elbow extension to occur in a controlled fashion. If this occurs too rapidly because of inadequate biceps control, overload can occur to the biceps muscle or biceps tendon or lead to avulsion, in which the biceps tendon anchors itself along the superior labrum. Injury to the labrum at this level has been identified as a SLAP lesion (19). The muscle kinesiological data collected have supported the theoretical basis for the mechanisms of injury to these various structures. This information can then be used on physical examination so that the clinician can reproduce symptoms in the phase where injury occurs. One then combines some basic physical examination findings based on observation and palpation with functional tests, such as the apprehension sign or testing the biceps during an eccentric load. Not only can an anatomic diagnosis be made of the injured structure, but a functional diagnosis can be made as well. One must also be careful to not confuse strength with motor skill. Adequate strength on manual muscle testing does not guarantee proper muscle function. Poorly developed muscle skill, proprioception, the proper agonist/antagonist balance during contractions, and the lack of proper timing of muscle firing can all contribute to an overuse injury. Any of these should be considered at least a potentially contributing factor.

To further shed light on a more complete biomechanical picture, the kinetic chain must also be considered. This

requires a sound understanding of the role each component of the chain plays during a skilled athletic maneuver. Any pathology at any point in the chain can alter the athlete's mechanics and lead to overload elsewhere. This may sound somewhat vague and generalized, but it is part of the functional approach practitioners working with athletes should consider. Throwers who have lost trunk/spine flexion/extension or pelvic/hip rotation may lose power from the loss of torque normally created during late cocking into acceleration phase or may have difficulty slowing down elbow extension during deceleration phase (20). Other components of the kinetic chain essential to minimizing trauma to the shoulder and arm are adequate neck rotation and eccentric strength of quadriceps. Compensation for restrictions in motion and relative weakness may lead to greater demands on power generated by the rotator cuff. This can create greater torque in the glenohumeral joint or require a greater and excessive eccentric contraction of the biceps. Eccentric overload of the biceps may injure the bicipital tendon of the labrum at its point of origin creating a SLAP lesion (19).

## EXAMINATION OF THE LUMBAR SPINE

### Inspection

The examination of the low back, like the other areas of the body, should begin as the patient enters the office and examination room. Watch how the patient moves while walking and how he or she moves changing positions. The patient's posture should be noted. The patient should be in a gown that opens in the back for full exposure. Look at the muscle bulk and symmetry of the low back. Also look at the skin for scarring or discoloration. Inspect the lumbar spine from behind and the side to assess for lordosis. Often, patients with stenosis may have hypolordosis because of spinal stenosis. Young athletes might have hyperlordosis because of an imbalance of paraspinal to abdominal strength.

### Palpation

The next step involves palpation of the muscles of the back, spinous processes, and important landmarks of the pelvis. From the back, the paraspinal muscles and the interspinous ligaments can be palpated. Palpate for the spinous processes, and in an older patient, these should be percussed to help in the diagnosis of a compression fracture. Finally, palpate for the bilateral posterior superior iliac spines (PSIS) to determine pelvis alignment. The examiner should place her thumbs on the bilateral PSIS and index fingers on the iliac crests. The height of the pelvis can be checked for alignment by comparing the two sides. Look for symmetry of bulk.

### Range of Motion

Range of motion should be tested both actively and passively if possible. Both are important in the evaluation of the low back. Range of motion should be checked in flexion,

extension, rotation, and side bending. If there is posterior pain to one side, the examination should include extension to both the left and the right to stress the zygapophyseal joints and to narrow the foramen in a patient with foraminal stenosis or a foraminal disc protrusion.

It is important to watch the spine during motion. In forward flexion, ask the patient to touch his or her toes and watch to see whether the motion comes from the spine or hips. Watch for reversal of the lumbar lordosis by inspecting the prominence of the spinous processes. In extension, look for the motion in the lumbar spine versus the hip and knees in many patients. While assessing range, ask the patient whether the discomfort is greater in flexion or extension. Be aware of conditions that can lead to spinal inflexibility like ankylosing spondylitis or diffuse idiopathic spinal hyperostosis (DISH).

Rotation and side bending can be evaluated next. The patient should be able to rotate his or her shoulders perpendicular to the pelvis. It is often helpful to stabilize the pelvis while the patient is rotating. Have the patient side bend next, and compare it to the opposite side. With each maneuver, the examiner can follow the active motion with active assisted motion to see to what degree the active motion is limited.

Examination of the hip joint and the muscles crossing it is an important part of the lumbar spine examination because of the intimate association with the pelvis and lumbar spine. Limited hip rotation may lead to increased rotatory forces in the spine. A tight rectus femoris may tilt the pelvis anteriorly, increasing the lumbar lordosis, whereas hamstring tightness may tilt it posteriorly and decrease it.

Maybe no other joint in the young person has seen more change in approach over the past few years than the hip. In evaluating the spine, the examiner should have an idea of any suspected loss of range of motion. In the older patient, the loss of range of motion, particularly internal rotation, needs to be documented, and the practitioner needs to determine how much that pain contributes to the patient's symptoms. In a younger patient, the loss of range of motion can be early osteoarthritis, but in the absence of joint space loss on plain film radiographs, it could be a soft tissue injury or a bony anatomy change. Studies have shown that labral tears can be seen in young patients with complaints of groin pain approximately 20% of the time (21). These lesions have a high association

<sup>a</sup>Primary innervating root and initial muscle tested are in bold.

with bony abnormalities (22) and could be precursors for osteoarthritis (23).

The examination of the hip should consist of at least three elements. The first standing on one leg or walking to look for dynamic weakness in the form of a lurch to the opposite side or compensation to the same side due to weakness. This can be checked in the side lying position statically. Next, the patient should be supine and simple range of motion should be checked at 90 degrees of hip and knee flexion. Finally, the hip should be checked in flexion at 90 degrees, adduction, and internal rotation for the presence of groin pain. Table 2-6 shows normal range of motion of the hip.

## Neurological

The examination of the low back always includes a full neurologic examination of the lower limbs. Radiculopathies can be very subtle, and as with the cervical spine examination, manual muscle testing, sensory examination, and reflexes all must be addressed to find these subtle changes. The order to proceed is examiner dependent. Similar to the cervical spine examination, manual muscle testing should also be confirmed with additional muscles when subtleties exist because the muscles of the lower limbs have two or more levels of innervation. However, unlike the upper limbs, the lower limb muscles can generate greater force. The examiner needs to provide enough resistance to detect subtle muscle weakness. In addition, heel and toe walking can be added to the gait examination to test the tibialis anterior and gastrocnemius-soleus muscles. Table 2-7 lists what should be included in manual muscle testing (19).

Reflexes can be addressed next. Table 2-8 lists what should be included in reflex testing (19).

<sup>a</sup>Primary innervating root.

Finally, sensation can be tested for both pinprick (lateral spinothalamic tract) and light touch (dorsal columns). Table 2-9 lists what should be included in sensation testing (19).

### Additional Tests

Examination of the low back should include special tests that are specific for certain pathologies. Every back examination should include a straight leg raise if there is concern about radiculopathy. The straight leg raise, also known as the Lasegue's test, can be performed with the patient seated or in the supine position. With the patient supine, raise the affected lower limb with the knee in full extension. Starting at 30 degrees of leg elevation, patients with nerve root irritation will begin to have discomfort. Stretch on the nerve will be maximal at 65 degrees, and pelvic rotation will begin. A positive test is pain down the limb to the knee in the arc of 35 to 65 degrees. For more subtle cases, ankle dorsiflexion can be added to maximize the nerve stretch.

## EXAMINATION OF THE KNEE

### Inspection

Inspection is only possible with adequate exposure. Begin by placing the patient in shorts or tying the gown up above the knee. The patient's gait should be observed first. Pay attention to the positioning of the knee on both the medial/lateral plane (valgus vs. varus) and the anterior/posterior plane (extension lag vs. knee recurvatum). Also, observe the joint above and below. Be sure to note any restrictions in the hip or ankle motion. Look at the foot for evidence of pes cavus (high arch) or pes planus (flat footed). The patient should then sit or lie on a table.

It is important to next look at the joint for any gross evidence of effusion or discoloration. Any changes can be evaluated further as the examination proceeds. Next, the examiner should assess for any muscle atrophy or fasciculations. If there is atrophy, the thigh or calf circumference should be measured and compared with the unaffected side. Finally, check the skin for any evidence of scarring from previous surgery of trauma.

### Palpation

Palpation of the knee should be done systematically. Begin either medially or laterally, and work across the knee. Address the skin, soft tissue, and bony aspects of the joint. Begin the examination by laterally palpating the overlying skin, which should move freely over the soft tissue and bones. The lateral collateral ligament can be palpated next. Palpate along the length of the ligament from the lateral femoral condyle to the insertion on the fibula. Have the patient cross the leg (FABER—Flexion of the knee to 90 degrees, ABduction and External Rotation of the hip) to better palpate the ligament. Moving more proximally, the biceps femoris tendon can be palpated as it comes down to its insertion on the fibular head.

Bony palpation should include the lateral tibial plateau, fibular head, and the lateral femoral condyle. All should be felt for tenderness or palpable osteophytes. In addition, the anterior portion of the lateral meniscus lies on the lateral tibial plateau and may be tender after an injury. This should be checked with the knee in 90 degrees of flexion. Moving across, the anterior portion of the knee should be palpated. Palpate over the prepatellar bursa (above the patella) and the superficial infrapatellar bursa (overlying the infrapatellar ligament). Next in the region is the patella. All four poles of the patella should be palpated, in addition to the undersurface of the medial and lateral aspects. Palpation of the medial and lateral facets of the patella can be performed with the patient lying supine and the knee completely relaxed. Tenderness or hypersensitivity is indicative of patellofemoral pathology. Furthermore, one should palpate the lateral retinacula for the presence of a synovial plica (Fig. 2-11). Proximally, the quadriceps muscle should be palpated for any discomfort or defects. Distally, the infrapatellar tendon should be palpated to its insertion on the tibia at the tibial tubercle.

The medial portion of the knee is addressed in a similar fashion. Palpate the skin, and palpate in the region of the pes anserine bursa (medial to the tibial tubercle and just above the insertion of the tendons of the sartorius, gracilis, and

**FIGURE 2-11.** Palpation of the lateral retinacula of the knee for synovial plica.

semitendinosus). Next, palpate the medial collateral ligament from its origin on the medial femoral condyle to the medial tibia. Moving proximally, the tendons of the sartorius, gracilis, and semitendinosus should be followed from their insertion to the muscle tendon junction.

Bony palpation medially should include the medial femoral condyle and the medial tibial plateau. As with the lateral tibial plateau, the medial meniscus can be palpated. This is made possible by internally rotating the tibia with the knee at 90 degrees and palpating between the tibial plateau and femoral condyle. Palpate for joint line tenderness medially and for any palpable osteophytes.

Before turning the patient, the joint should be checked for an effusion. With the patient in the supine position, with the leg in full extension, place the examiner's thumb on the medial side below the patella. Compress the suprapatellar pouch and lateral knee to accumulate fluid on the lateral side. Compression medially should give a sense of fullness laterally. In addition, the patellar ballottement test can be performed. Using both hands, the proximal hand starts 10 cm above the patella with the thumb lateral and fingers medial. The distal hand starts 5 cm below with the same orientation. While compressing the tissues, the hands are slowly brought toward each other. When they are just above and below the patella, the index finger from the distal hand taps the patella. Without an effusion, the patella will be in the femoral condyles and there will be no findings. With an effusion, the patella will "tap" onto the femur and the examiner will feel the sensation.

The last region to be inspected is the posterior aspect of the knee. This is done best with the patient in the prone position. Palpate for the boundaries of the popliteal fossa, which include medially the semitendinosus and semimembranosus muscles. Laterally palpate for the biceps femoris muscle and inferiorly the two heads of the gastrocnemius. Within the region of the popliteal artery are the popliteal vein and posterior tibial nerve. Palpate for any popliteal cysts, which is best done with the knee in extension.

### Range of Motion

Range of motion of the knee should be approximately 135 degrees of flexion and 0 degrees of extension. Both internal and external rotation should be approximately at 10 degrees. Loss of range of motion can be of traumatic or degenerative causes. It is important to check both active range of motion and passive range of motion. A patient with quadriceps weakness may be unable to achieve full active extension but with the examiner's assistance has full range of motion.

The testing can be performed with the patient seated on the edge of the examination table to start. Check the active and passive extensions (this can be incorporated into the manual muscle testing). Watch the patella during extension for its position in the trochlear groove. Active flexion can also be tested in this position, but passive flexion is better tested with the patient in the supine position. Loss of terminal flexion and extension can also be attributed to a joint effusion.

**TABLE 2.10 Manual Muscle Testing of the Knee<sup>a</sup>**

L4,5	<b>Extensor hallucis longus</b> , gluteus medius

<sup>a</sup>Primary innervating root and initial muscle tested are in bold.

### Neurological

The neurologic examination should consist of manual muscle testing, sensation, and reflexes. The manual muscle testing is performed to test quadriceps strength by extending the knee. Hamstring testing should be performed with the patient flexing the knee while sitting. Another useful test is a step down test. Watch the patient step down from a foot stool in the room to assess his or her control descending and the amount of increase in the Q angle. Table 2-10 lists what should be included in manual muscle testing (24).

Reflexes can be addressed next. Table 2-11 lists what should be included in reflex testing (24).

Finally, sensation can be tested for both pinprick (lateral spinothalamic tract) and light touch (dorsal columns). Table 2-12 lists what should be included in sensation testing (24).

### Ligament Stability

Stability of the ligaments should be tested with the patient relaxed and in a supine position. Beginning with the collateral ligaments, the examiner should firmly grasp the distal leg and provide a valgus (laterally applied) force to the knee. This will test the medial collateral ligament. The test should be completed with the knee in 20 to 30 degrees of flexion and also with the knee in full extension to test medial capsular integrity (Fig. 2-12). Remember to apply three points of pressure, one being distal lateral leg, the next lateral knee, and finally distal medial knee to maintain control of the leg. If possible, palpate around the knee, and palpate the ligament for a defect during the application of a valgus force.

In a similar fashion, apply a varus (medially applied) force to the knee to check the lateral collateral ligament. Again, it is helpful to place a finger on the ligament during the maneuver. It is also important to apply three points of pressure. As with the medial side, check in full extension and in 20 to 30 degrees of flexion.

The anterior and posterior cruciate ligaments should be examined next. The Lachman's maneuver is the most sensitive

**TABLE 2.11 Reflex Testing of the Knee**

S2	Popliteal fossa

<sup>a</sup>Primary innervating root.

test for injury to the anterior cruciate ligament (ACL). The test is performed by firmly grasping the distal lateral thigh with the outside hand in a supine patient. The knee is then placed in slight flexion, approximately 30%. Next, the proximal medial leg is grasped by the examiner's inside hand and slightly laterally rotated. A quick upward force is then applied to the tibia by the inside hand while the thigh remains stabilized by the outside hand. The examiner is feeling for a sharp end point of the ACL. This examination maneuver is difficult and must be practiced many times before it can be done correctly (Fig. 2-13), but this is the most accurate method of judging the integrity of the ACL (25).

With the patient in a supine position and the hip flexed at 45 degrees while the knee is in 90 degrees of flexion, the examiner can test both the posterior and the anterior cruciate ligaments. The foot is stabilized when the examiner sits on the patient's foot. To test the ACL, the examiner grasps around the proximal tibia and places the thumbs on the medial and lateral tibial plateaus. The tibia is then pulled anteriorly with respect to the femur. The amount of anterior movement should be minimal and equal to the opposite side. The movement is compared with the opposite knee.

Testing of the posterior cruciate ligament is completed just after the ACL. With the patient supine, the hip is flexed to 45 degrees and the knee flexed to 90 degrees. The foot is immobilized by the examiner sitting on the foot. The examiner then

**FIGURE 2-12.** Evaluation of the stability of the collateral ligaments of the knee.

**FIGURE 2-13.** Evaluation of the stability of the ACL of the knee.

gives a posteriorly directed force to the tibia with the thumbs on the tibiofemoral junction. As with the anterior drawer test, the laxity is compared with the opposite side. Another indication of a posterior cruciate tear is hyperextension of the knee joint. This can be observed with the patient supine and the hip and knee flexed at 90 degrees. The examiner elevates the leg by lifting the heel with all muscles relaxed. Again, both sides should be tested for comparison.

The posterolateral complex of the knee includes the posterolateral capsule, the popliteus muscle, and the lateral collateral ligament. When one or more of these structures are injured, particularly in the setting of a posterior cruciate ligament deficiency, the knee becomes susceptible to rotatory instability. Posterolateral complex laxity can be demonstrated by examining the tibial external rotation with the knee flexed at 90 degrees and comparing it with the contralateral side.

### Medial and Lateral Menisci

The medial and lateral menisci may account for the second most commonly injured structures in the knee, second only to the patellofemoral joint (PFJ) as a source of knee pain in the younger patient groups. Rotatory motion, particularly when combined with compression, is felt to be the common biomechanical factor leading to injury. An aging and degenerative meniscus is probably more susceptible to this type of trauma. Commonly, injury to the meniscus will result in an effusion, making the detection of an effusion an important clinical test when looking for meniscal injury. Joint line tenderness is sensitive for meniscal injury but not specific. The posterior horns are loaded during flexion so that simultaneous knee flexion and rotation will be sensitive for pain secondary to a posterior horn meniscal tear. Pain associated with the internal tibial rotation tends to be more indicative of injury of the lateral meniscus, whereas external rotation may be more suggestive of the medial meniscus.

A test for meniscal injury would be the McMurray's test (26). McMurray's test is performed with the patient supine.

**FIGURE 2-14.** Evaluation for meniscal injury or McMurray's test of the lateral meniscus for the knee.

The knee is brought into full flexion, and the tibia is internally rotated and then extended to 90 degrees while being held internally rotated. An audible pop, click, or locking is considered a positive McMurray's test and felt to be specific for posterior horn bucket handle lateral meniscal tear. Externally rotating the tibia and performing the same motion will detect injury to the posterior horn of the lateral meniscus (Fig. 2-14).

### Biomechanics of the Knee

The knee appears to function primarily as a hinge joint, but with closer observation, its biomechanics are more complex. Rotatory motion also occurs and, although very limited, may play an important role for many of the acute traumatic and chronic overuse injuries. The primary static stabilizers include the anterior cruciate and posterior cruciate ligaments, the posterolateral complex, the remaining capsular structures, and, to a lesser extent, the medial and lateral menisci. The role of the dynamic stabilizers of the knee in controlling rotatory motion has not been well studied. However, it does appear that the medial hamstrings, lateral hamstrings, and popliteus muscles play a role here in dynamic rotary stabilization. Although knee muscle kinesiology has been extensively studied, the great majority of work has been looking at the biomechanics of the PFJ (27–33). This is not surprising, considering that patellofemoral syndrome is the most common knee disorder causing pain and limiting function.

There is no other musculoskeletal disorder in which the kinetic chain plays a greater role or requires a more thorough analysis than with patellofemoral-related pain. It is widely believed that the relative position of the patella in the PFJ, how it sits at rest, and how it travels during dynamic activities can contribute to patellofemoral syndrome and be a risk factor for patellofemoral subluxation/dislocation (26,34). The quadriceps muscles are the primary knee extensors, with a small contribution coming from some fibers of the adductor magnus (35). Three muscles of the PFJ—the vastus lateralis (VL), the vastus medialis, and the vastus intermedius—cross

only the knee joint and are relatively fixed in their line of pull. Tightness in the lateral or medial retinacular structures can somewhat alter this. The hip joint is the primary rotator of the lower limb, and the degree of rotation may play an important role in patella tracking disorders. The fourth quadriceps muscle, the rectus femoris, is a two-joint muscle that crosses the hip in addition to the knee joint. It originates from the anterior superior iliac spine (ASIS), and calculating the Q angle reflects its line of pull. The Q angle is measured by extending a line from the ASIS to the midpoint of the patella. One measures the angle created by the intersection of the second line that connects the midpoint of the patella to the tibial tubercle. The normal Q angle is 10 to 14 degrees, and any significant deviation from this may lead to improper patella tracking and subsequent PFJ pain. External rotation of the hip decreases the Q angle, whereas internal rotation increases it. During normal gait mechanics, ankle pronation occurs simultaneously with hip internal rotation; conversely, supination occurs with hip external rotation. Therefore, hyperpronation can increase the Q angle, whereas hypersupination can decrease it.

EMG has been used to study knee muscle function, primarily looking at the balance and relationship among the VL, vastus medius (VM), and vastus medialis oblique (VMO), and to better understand patellofemoral maltracking syndromes (27,36–39). Szczepanski et al. (38) compared VMO and VL EMG activity during concentric and eccentric isokinetic exercises in asymptomatic individuals and found a greater VMO/VL ratio only during concentric contractions at 120 degrees per second. Reynolds et al. (37) studied asymptomatic women and found no difference in the VMO/VL relationship through full range of motion. In a study that looked at the effect of Q angles, Boucher et al. (27) found no significant differences in VMO/VL EMG ratio between asymptomatic volunteers and patients with patellofemoral maltracking syndromes. They did find a decrease in the VML/VL ratio in a subset of patellofemoral syndrome (PFS) patients with Q angles greater than 22 degrees at 15 degrees of knee extension. Voight and Wieder (39) compared the reflex response times of the VMO and VL EMG following a tendon tap. There was an increase in the VL response times in patellofemoral maltracking syndrome patients. These studies are far from conclusive, and the debate about the relationship between the VMO and the VL as contributing factors for patellofemoral disorders continues, while conventional clinical management remains based on these principles.

Kinesiological work has also been done to better understand muscle mechanics as it pertains to patients who have torn their ACLs and to help determine the most effective methods of managing these patients both nonsurgically and postoperatively. The ACL restrains anteromedial rotation of the tibia. An EMG study by Limbard et al. (40) on ACL-deficient patients found an increase in biceps femoris activity with a simultaneous decrease in quadriceps activity during swing-to-stance transition at normal walking speeds. At this point in gait, the hamstring may have been firing to prevent anteromedial tibial rotation. The hamstrings were less active

in these patients from midstance to terminal stance. Branch et al. (41) found an increase in EMG activity of the lateral hamstrings in ACL-deficient patients during swing phase and an increase in medial hamstring and a decrease in quadriceps activity during stance phase. Tibone et al. (42) had reported similar findings. Solomonow et al. (43) stressed that an intact ACL led to excitement of the hamstrings and inhibition of the quadriceps. Baratta et al. (44) studied coactivation patterns. Hypertrophy of the quadriceps impaired hamstring coactivation, and strengthening of the hamstrings reduced this. Lutz et al. (45) demonstrated a greater ability to perform cocontractions of the hamstrings and quadriceps during closed kinetic chain exercises, thus conferring more stability to the knee. Weresh et al. (46) studied the popliteus muscle and found no difference in activation between ACL-deficient patients and controls.

Based on these EMG studies, one can now look for some of the muscle imbalances and other anatomic factors for patellofemoral maltracking syndromes such as hyperpronation or excessive hip internal rotation during the physical examination. Once these findings have been identified, they can then be more specifically addressed with physical therapy or some other form of a structured exercise program.

## SUMMARY

The physical examination is one of the most basic and valuable clinical tools of a physician. A trend to spend less time examining patients and more money on tests is the result of the increasing demands on physicians' time and the technological advances in medicine. We believe the manual skills of the physiatrist and the comprehensive physical examination performed are basic and unique to the clinical care that physiatrists offer. This chapter has attempted to review some of the basic traditional clinical examination skills in conjunction with the entire kinetic chain. We have also incorporated some of the relevant biomechanical and kinesiological components that can help the physician approach the physical examination in a more functional manner.

# Assessment of Human Muscle Function

*To move is all mankind can do, and for such the sole executant is muscle.*

Sir Charles Sherrington, Edinburgh, 1937–1938

The relevance of skeletal muscle to the performance of all types of physical activities (i.e., therapeutic, recreational, occupational, and others) and the successful participation in daily life and societal obligations should be well appreciated by all those who work in rehabilitation. Skeletal muscle plays an important role, primary and/or secondary, in the pathophysiology of many diseases, and skeletal muscle function is key to defining the nature and extent of impairments and activity limitations. Thus, understanding how to measure skeletal muscle function and how to interpret the results of various physiologic and functional tests is a necessary component of the education of all physiatrists and rehabilitation professionals. It is worth noting that this understanding is of special value to the advancement of research in the rehabilitation sciences because many biological and functional outcome variables used in scientific studies are directly associated with the function and structure of skeletal muscle. Finally, this chapter discusses this topic in the context of what is known about human skeletal muscle in health and disease. We will not review the extensive literature on muscle function based on studies in various animal models. With very few exceptions, the references will be those from human studies.

## WHY MUSCLE?

The main function of the approximately 600 muscles in the human body is to convert chemical energy (i.e., fat and carbohydrates) into mechanical energy and thereby generate force. This force is transmitted from the active muscle fibers to the tendons with the help of the sarcolemma, special extracellular protein complexes, and connective tissue elements. The action of the tendons on bony structures results in the conversion of the force into joint and limb movement and displacement of individual body parts or the body as a unit. In principle, force generation can occur during brief moments, resulting in what is generally referred to as *muscle strength*, or force generation can be maintained over a period of time referred to as *muscle endurance*. In the clinical setting, the failure to generate force during a brief moment is what we generally call *muscle weakness*, as opposed

to the inability to maintain force, which we refer to as *muscle fatigue*.

Skeletal muscle comprises 40% to 45% of the total body mass (1–3), and 55% of total muscle mass is distributed in the lower limbs. Muscle contains approximately 50% of the total body protein (4), and protein turnover in muscle represents 25% of the total body protein turnover (3,5). More than half of the protein in muscle is found in the thick (myosin) and thin (actin) contractile filaments that generate and regulate force production (4,6). Actin and myosin account for more than 80% of the protein in the myofibrillar complex. In addition to force generation, skeletal muscles contribute to basal metabolism; produce heat to maintain core temperature; regulate blood glucose; serve as storage for carbohydrates, lipids, and amino acids; contribute to energy production during exercise; and protect internal organs (7).

During illness, nitrogen must be mobilized from muscle to provide amino acids to the immune system, liver, and other organs. Thus, if sufficient nitrogen is not available due to muscle wasting associated with aging, immobilization, or severe illness, the body's capacity to withstand an acute insult declines. The relationship between muscle function, illness, morbidity, and mortality is more obvious if one considers that morbidity becomes demonstrable at a 5% loss of lean mass and that the loss of 40% of lean body mass (LBM) is fatal (8). Finally, the extensive and considerable plasticity demonstrated by skeletal muscle under various conditions and in response to environmental influences such as bed rest, exercise training, and electrical stimulation makes it an ideal target for therapeutic and rehabilitative interventions.

From a functional point of view, skeletal muscle strength has been associated with comfortable and maximal walking speed (9,10), the incidence and prevalence of disability (11–13), balance (12), time to rise from a chair (14,15), ability to climb stairs (16), incidence of falls (17), and survival rate (18,19). Muscle power, a related but distinct property of skeletal muscle, also shows a positive and significant association with functional status (20). This evidence provides strong support to the conclusion that enhancing and maintaining muscle strength and muscle endurance throughout the life span, whether it is through prevention or rehabilitation, may reduce the prevalence of limitations in recreational, household, daily, and personal care activities, both in health and disease (21).

## MUSCLE ACTIONS AND UNITS OF MEASUREMENT

The need to use consistent terminology, definitions, and measurement units across research studies, in educational programs, and in clinical rehabilitation is of great importance. Furthermore, measuring devices must be reliable and valid indicators of muscle function. Muscle function and structure can be quantified using the International System of Units, a refinement of the metric system (22–24) (Table 3-1).

All types of muscle actions result in the production of force or torque (tendency of a force to produce rotation about an axis). When the force is applied against an immovable object and there is no joint angular movement, the action is called *static* (isometric). Work is defined as the product of force  $\times$  distance, and power as the ratio of work over time. Therefore, by definition, because during a static muscle action the distance is zero, no work is performed and no power is produced.

When the muscle action results in the displacement of a given mass or body part at the same time that the origin and insertion of a muscle move *closer together*, the action is called *dynamic* (isotonic) *concentric* or *shortening* action. When the action results in the displacement of a given mass, and the origin and insertion of a muscle move *further apart*, the action is called *dynamic eccentric* or *lengthening* action. Both concentric and eccentric muscle actions result in work (force  $\times$  distance), positive in the first case and negative in the latter. During many natural activities such as walking and running, concentric muscle actions occur in immediate combination with eccentric actions and are referred to as the *stretch-shortening cycle* (25,26).

In these activities such as jumping and running upstairs, the rate at which force is developed is more important than generating maximal force. Thus, power ([work/time] or [force  $\times$  velocity]) and not strength becomes the limiting factor. Some of the most important physical and biomechanical concepts in the study and measurement of muscle function are illustrated in Figure 3-1 (27).

Isokinetic muscle actions are dynamic and could be concentric or eccentric. This kind of muscle action is characterized by a combination of constant angular velocity and variable

**FIGURE 3-1.** Physical and biomechanical concepts relevant to the assessment of human skeletal muscle function. Note the relevance of time on several variables, such as displacement, velocity, and work. Also, note the sequence of formulas leading from mass to power (27).

resistance. The resistance generated by the isokinetic device varies throughout the range of motion in order to match the torque generated by the muscle at each angle of the range of motion. It should be recognized that isokinetic actions represent an artificial situation that does not usually occur in nature outside of a laboratory. Many devices have been developed to measure muscle torque, work, power, and endurance based on the isokinetic concept. Isokinetic dynamometers, although expensive, are found in many research laboratories as well as in rehabilitation clinics (Fig. 3-2). Advantages of these devices

**FIGURE 3-2.** Picture of an isokinetic dynamometer. Here, the torque of the ankle dorsiflexor muscles is measured.

**TABLE 3.1** Examples of Units for Assessing Muscle Structure and Function

Mass	Kilograms (kg)
Distance	Meter (m)
Time	Second (s)
Force (mass $\times$ acceleration)	Newton (N)
Work (force $\times$ distance)	Joule (J)
Power (force $\times$ velocity)	Watt (W)
Velocity	Meters per second (m/s)
Torque	Newton-meter (Nm)
Angle	Radian (rad)
Angular velocity	Radians per second (rad/s)
Volume	Liter (L)

include the objective quantification of muscle function, the immediate availability of reports, the provision of feedback to the patient, their high reproducibility, and the opportunity to standardize sequential testing for follow-up purposes during the rehabilitation process. Disadvantages include the cost, lack of portability, and limited specificity in relation to muscle actions typical of daily activities.

The terms *open kinetic chain* and *closed kinetic chain* are used to describe two forms of muscle contractions and movements. The kinetic chain is a concept that describes a body segment as a series of mobile segments and linkages (28–30). In the case of the lower extremities, this chain allows forward propulsion during gait. When the foot is in contact with the ground, the kinetic chain is considered to be closed. When the foot is off the ground, the chain is said to be open. Examples of open kinetic chain exercises used in rehabilitation programs are leg extension, leg curls, arm curls, and bench press exercises. Exercises such as leg press, squats, and push-ups are examples of closed kinetic chain exercises. Closed kinetic chain exercises tend to activate agonist and antagonist muscle groups simultaneously (e.g., the knee extensors and flexors during squat exercises) and tend to be more functional (31). Both types of exercises could result in significant functional improvements after reconstruction of the anterior cruciate ligament (30).

### Energetics of Muscle Actions

The energy needed for the muscle to perform its mechanical functions is supplied by three different energy-producing biochemical pathways (Fig. 3-3). The relative contribution of each pathway is determined by the duration and intensity of the muscle actions. Performance of a particular task is determined not only by the integrity and capacity of the sarcomeric proteins but also by the ability of these pathways to supply adenosine triphosphate (ATP). Thus, the results of the functional tests discussed later could be used as indicators

**FIGURE 3-3.** Schematic drawing of the three different biochemical pathways for the energy production in skeletal muscles.

of the status of the biochemical pathways. The low strength and/or endurance performance scores in patients with various neuromuscular diseases may relate to abnormalities in these pathways.

In general, short-duration tasks lasting up to 10 seconds depend on existing stores of ATP and creatine phosphate (CP) (32,33). These two stores are readily available and therefore could be used instantaneously. However, from a quantitative point of view, these ATP and CP stores are very small and have a limited ability to sustain muscle performance over time. Activities lasting between 10 seconds and 2 minutes are driven by the process of anaerobic glycolysis fueled by the transport of glucose into the muscle cell or the breakdown (glycogenolysis) of intramuscular carbohydrates (34–38). Finally, the energy for activities lasting more than 2 minutes is supplied mainly by the oxidative pathways in the mitochondria (Fig. 3-4). The fuel for these pathways can be derived from the end product of anaerobic glycolysis, circulating fatty acids, or intramuscular lipid stores (39,40).

In real life, these biochemical processes combine in various proportions to provide ATP during physical activity and exercise. Activities can be classified as “predominantly” dependent on a particular pathway, since very few activities can be considered purely dependent on any given pathway.

**FIGURE 3-4.** Sequence of activation of energy-supplying biochemical pathways in relation to the duration of physical activity. More than one pathway may be active at a given point in time. At the point of transition (e.g., 10 seconds, 2 minutes) there is significant overlap among systems. Total energy output per unit time (power) declines over time as the oxidative pathways become the predominant source of ATP. The transitions do not have to be unidirectional, since, for example, activation of the glycolytic pathways may be necessary at a particular point in time during the performance of a predominantly oxidative activity (46).

In other words, a given activity may require a combination of all three processes, depending on fluctuations in the intensity of the exercise. For example, when a person is walking on a level at a comfortable speed, ATP supply may depend predominantly on oxidative pathways. Confronted with an incline or hill, the contribution of the glycolytic pathways increases. Another example in a different type of activity is the sprint at the end of a marathon race requiring the activation of the glycolytic pathway in a predominantly oxidative event.

### Functional Characteristics of Skeletal Muscle

#### Muscle Strength

Muscle strength can be defined as the maximal force (or torque) generated by a muscle or muscle group at a specified velocity. Because strength depends on force production, it is generally measured in newtons (N) or newton-meters (Nm) in the case of torque. When reporting measurements of muscle strength, the type of muscle action must be stated (24). In other words, strength can be static (at different joint angles), dynamic (concentric or eccentric), or isokinetic (at different angular velocities).

It should be clear that there is no single strength measurement and that different kinds of strength can be expressed. Furthermore, under static conditions, force is influenced by fiber (and sarcomere) length (41) and mechanical leverage. Moreover, under dynamic conditions, the level of force is influenced by the velocity of the movement (41). These relationships are two of the most fundamental biologic properties of skeletal muscle and must be understood to appreciate the meaning of the results of functional tests. For example, the patient's performance during a manual muscle test will not be reliable unless the test is always done at the same joint angle.

The force-length relationship illustrates how the sarcomere length, which defines the degree of overlap between actin and myosin and the formation of cross-bridges, determines force (Fig. 3-5). The optimal sarcomere length varies with the type of activity. For example, the optimal sarcomere length has been reported to be in the region around the plateau for ankle bending (42), walking (43), and jumping (44) activities and in the descending limb for slow pedaling (45). On the other hand, the force-velocity curve demonstrates a gradient of strength that ranges from the highest level during fast eccentric actions to the lowest level during fast concentric actions (Fig. 3-6). Static actions generate more than dynamic concentric actions but less force than dynamic eccentric actions, independent of the velocity.

#### Testing of Muscle Strength

Various methods and devices are used to measure the different types of muscle strength (46). These methods used in clinical practice and research require a maximal voluntary action on the part of the patient or volunteer. This is dependent on the ability of higher central nervous centers to recruit and modulate the frequency of discharge of the appropriate spinal motoneuron pool. The implication is that all those factors that

**FIGURE 3-5.** Force-length relationship of skeletal muscle. *Insets* show schematic representations of cross-bridges. An optimal length results in the largest number of actin-myosin cross-bridges (plateau). When the muscle (or sarcomere) has been stretched too much (descending limb; sarcomere length  $>3.0 \mu\text{m}$ ), no active force is produced by the actin-myosin cross-bridges. However, a level of force can be recorded as a result of the contribution of the passive elastic elements, including cytoskeletal proteins such as titin and nebulin and components of the sarcolemma. During the ascending limb (sarcomere length  $<1.75 \mu\text{m}$ ), overlap of myofilaments interferes with actin-myosin cross-bridge formation (41).

influence the activation of the neuromuscular system such as age, various disorders in the central and peripheral nervous system, presence of pain, joint swelling, medications, fear and anxiety over the test, lack of motivation, time of the day, and environmental conditions such as noise may have a significant effect on strength measurements and should be controlled for

**FIGURE 3-6.** Force-velocity relationship of skeletal muscle. *Insets* show schematic representations of actin-myosin cross-bridges. Static (isometric) strength (relative shortening velocity = 0) is higher than force at any given velocity of movement during concentric (shortening) muscle actions. On the other hand, eccentric (lengthening) muscle actions at any given velocity generate higher forces than static actions (41).

or factored into the analysis of the results (47–49). Needless to say, testing conditions must be standardized as much as possible, the same device and/or method and testing protocol must be used when repeated measurements are required, the subject must be encouraged to make a maximal effort during the test, and the presence of symptoms such as pain should be considered when interpreting the measurements. Furthermore, for comparisons among groups, it may be necessary to adjust for differences in muscle/body size using statistical techniques (50). Even under optimal conditions, a valid and reliable level may require that the strength test be repeated more than once (51). Over the last decade, there has been a growing interest in, and a gradual development of, the statistical methods for the analysis of reliability. Today, there is a general agreement that a comprehensive set of several statistical methods are required to fully address the reliability of a measurement method (52).

### Manual Muscle Testing

The method of muscle strength measurement used most frequently in the busy clinical setting is manual muscle testing. This technique uses a subjective scale (Table 3-2) that ranges from zero (complete paralysis) to normal strength (erroneously called *normal muscle power* by some authors) and is generally known as the “Classification of the Medical Research Council of Great Britain” (53,54). The tester’s perception of the strength of a given muscle is influenced by the duration of the tester’s effort and the force applied during the test (55). The manual muscle testing scale is characterized by a fairly high level of intra- and interrater variability that limits its usefulness for research studies and clinical follow-up (56). To distinguish among the various degrees of muscle strength within a given level, this scale has been modified with the addition of intermediate levels (e.g., 4+ and 4–). Although clinically useful, there is no evidence that this modification increases the validity or the reliability of the method. It should be understood that this method represents an estimate of static strength at the tested joint angle. Extrapolation of the results to other joint angles and especially to dynamic actions must be done with great caution.

### Static (Isometric) Maximal Voluntary Contraction

A static maximal voluntary contraction (MVC) refers to a condition in which a person attempts to recruit as many muscle fibers in a muscle as possible for the purpose of developing

force (24). Although the need for a maximal voluntary effort applies to all forms of strength testing, the term *maximal voluntary contraction* is frequently associated with static strength testing (57). Devices such as hand-held dynamometers, cable tensiometers, force transducers, and isokinetic (angular velocity set at zero) dynamometers can be used to measure static muscle strength. Several studies (58–60) have shown good intra- and interrater reliability for the hand-held dynamometer in various patient populations. The simplicity and portability of these devices make it an attractive clinical instrument.

The validity of the strength measurement depends on the activation level of the nervous system. Merton (61) introduced the use of electrical stimulation superimposed on a static maximal effort in an attempt to activate directly those motor units and muscle fibers not stimulated by the voluntary effort of the subject. The stimulus is applied to the motor nerve during the MVC, and if the force increases, it indicates a suboptimal activation of motor units by the central nervous system. This is often referred to as *central activation failure* (CAF) (62). In many studies, single impulse stimulation has been used to detect CAF. It has been shown that high-frequency maximal train stimulation may improve the detection of CAF during static (isometric) knee extensions (57,62). This may be important in the clinical assessment of weakness, as it may distinguish weakness caused by CAF from that due to muscle wasting. This, in turn, could have very important implications for the design and evaluation of effective muscle-strengthening exercise therapy. The simultaneous assessment of CAF and muscle mass is advantageous and will facilitate the identification of the mechanism underlying muscle weakness in a particular patient. It is generally considered that healthy men and women even above the age of 70 have the ability to fully activate their muscles during an MVC (63,64).

### Repetition Maximum

During the course of physical rehabilitation and research studies involving exercise training, muscle strength is frequently measured using the one repetition maximum (1 RM) method. In the case of the extensors of the knee, DeLorme (65) defined the 1 RM as the maximum weight that can be lifted with one repetition with the knee going into complete

**TABLE 3.2** Scale for Manual Muscle Testing

Numeric Scale	Descriptor	Original Scale	Comments
0	Zero	No contraction	Complete paralysis
1	Trace	Flicker or trace of contraction	No palpable muscle action
2	Poor	Active movement with gravity eliminated	Some authors require full range of movement
3	Fair	Active movement against gravity	Some authors require full range of movement; no resistance
4	Good	Active movement against gravity and resistance	Examiner can overcome
5	Normal	Normal strength	Examiner cannot overcome

RM	3	6	10	12	20	25
Strength/power			Strength/power		Strength/power	Strength/power
High-intensity endurance			High-intensity endurance		High-intensity endurance	High-intensity endurance
Low-intensity endurance			Low-intensity endurance		Low-intensity endurance	Low-intensity endurance
Maximal power output	← to →				Low power output	

**FIGURE 3-7.** Theoretical repetition maximum (RM) continuum. Note the relationship between the number of repetitions and the specific muscle physiologic characteristic affected by training at the specific level (67).

extension. The proper unit of strength measurement is the Newton (N), but in this test, strength is commonly expressed as the mass in kilograms (kg) of the lifted load. This is a simple, valid, and reliable method that uses relatively inexpensive equipment and has been shown to be safe even in the elderly population (66). One drawback is that, by definition, it requires full active range of motion, a condition that some patients with joint pain, swelling, or contractures may be unable to satisfy. Also, if the test is not properly performed and too many repetitions are used to determine the 1 RM, muscle fatigue may interfere with the subject's ability to generate maximal force.

The concept of a continuum of repetition is frequently used when designing strength-conditioning programs (67). The RM refers to the exact resistance that allows a specific number of repetitions to be performed. Figure 3-7 shows the relationship between RM, number of repetitions, and muscle physiologic characteristic affected by training at a specific level.

### Isokinetic Strength

A number of isokinetic devices have been used to measure muscle strength in research laboratories and rehabilitation clinics (see Fig. 3-2). Although several muscle groups have been studied with these devices, most of the information concerns the knee, ankle (Fig. 3-8), and shoulder muscle groups. The lever arm is aligned with the axis of rotation of the joint to be tested, and proximal and distal segments are stabilized using Velcro straps limiting the contribution of agonists. The tester sets the angular velocity (available range 0 to 450 degrees per second or 0 to 7.9 rad per second), and the research subjects or patients are usually asked to complete three to five maximal repetitions, with the maximal torque used as a measurement of strength.

Individual brands of isokinetic dynamometers have been shown to be reliable (48,49,51,68–70), including measurements of isokinetic eccentric strength (49,69) and strength in patients with Duchenne or Becker muscular dystrophies (71) or stroke (72). Reliability is usually best at low angular velocities and gradually decreases with increased angular velocity. At very high velocities (e.g., above 180 degrees per

**FIGURE 3-8.** A hand-held goniometer is used to define 0 degrees of the ankle joint (i.e., the tibia being perpendicular to the sole of the foot) before the assessment of isokinetic torque in the ankle dorsiflexor muscles.

second), reliability is often considered poor. The comparison of strength values among the different brands of isokinetic dynamometers appears to be less valid. The spectrum of indicators of muscle function provided includes measurements of muscle work (integrated area under the curve), endurance (see later), agonists/antagonists ratios, and differences between sides that can be used to assess for muscle imbalances and asymmetries. On the other hand, the devices are expensive, the isokinetic nature of the muscle action does not allow for direct comparisons with daily activities, and the range of angular velocities does not extend to the speed of many sports and daily actions.

Finally, measurements of isokinetic strength at various angular velocities have been used to study, in vivo, the whole muscle torque-velocity curve and the effects of strength training on muscle contractile behavior (73–75). These studies require the use of torque at multiple given joint angles rather than peak torque over the continuum of available angles in order to control for the effect of muscle length on force development.

### Muscle Power

Leg extensor power could be a very important measurement in sports as well as in rehabilitation because power is more relevant for time-dependent/time-critical activities than strength. Power has been shown to correlate with gait speed, time to rise from a chair, stair-climb time, and self-reported disability (76,77). In addition, power declines with aging at a faster rate than strength (78). The maximum leg extension power output produced by both legs and each leg separately can be estimated using a power rig bench or resistance training machines. The power rig bench measures force and velocity

of leg movement, whereas the test using resistance training machines is based on the performance of one repetition at a percentage of the 1 RM. Peak power has been reported to occur usually at 70% of the 1 RM using the resistance training machines (20). Several test trials are usually performed with a 45- to 60-second rest between trials and the maximum value recorded. The coefficient of variation of this method is 6% (79).

Other investigators have designed power tests that combine an eccentric muscle action followed by a concentric action of the same muscle group with a very brief static action in between (80). This is a test of the stretch-shortening cycle (81). A mat or platform that is connected to a timer is used to measure flight time (time spent off the ground) during a vertical jump from which jump height can be calculated. The jump is preceded by a countermovement or semisquat position. The output is fed into a computer for analysis and calculation of muscle power.

### Muscle Endurance (and Fatigue)

The definitions of *endurance* and *fatigue* vary with the source. For the purpose of this chapter, *endurance* will be defined as the “time limit of a person’s ability to maintain either an isometric force or a power level involving combinations of concentric and/or eccentric muscular actions” (24). Endurance can be measured in seconds. Fatigue, on the other hand, is the inability to maintain a given level of force output (82). Alternatively, *neuromuscular fatigue* can be defined as “any reduction in the force-generating capacity of the total neuromuscular system” and can be due to factors that affect muscle fibers, the neuromuscular junction, and/or the nervous system (83). In humans, fatigue results in the loss of voluntary force and power production (84), a reduction in electrically stimulated maximal force and the maximum rate of force development (85), altered recruitment pattern of muscles (86), impaired neuromuscular performance in activities such as jumping (87), and even a reduction in sensory function such as the acuity of the joint movement sense (88). Methods used to measure these effects could be good indicators of the presence and degree of fatigue in younger and older populations (89).

In the context of the study of muscle performance, endurance could be divided into central (cardiovascular) and peripheral (local muscular) types. Several physiologic systems are involved in the expression of endurance and the avoidance of fatigue, including the nervous (central and peripheral), cardiovascular, hormonal, and metabolic systems. It is likely that the contribution of each system to endurance and fatigue depends on factors such as the type of activity, environmental conditions, nutritional status, and fitness level. Measurements of muscle endurance represent an integrated evaluation of several of these systems.

The basic mechanisms underlying muscle fatigue have not been precisely defined, although our understanding of this phenomenon has been substantially enhanced by recent research. Several excellent reviews summarize the available literature and discuss the contribution to fatigue of many of the

components of the neuromuscular system (90–92). Clearly, each and every step along the chain of transmission of the electrical and chemical signals from the brain to the actin-myosin cross-bridges and the biochemical pathways that supply fuel for muscle action is a potential site of failure. The development of fatigue is significantly influenced by the fiber type composition of skeletal muscle as the effector organ (93). Other relevant factors include central and peripheral mechanisms (94), such as changes in the excitability of the motor cortex or inadequate neural drive upstream of the motor cortex (95,96). This type of fatigue is of particular significance in neurologic rehabilitation, as it is considered prevalent in various nervous system disorders such as multiple sclerosis and stroke (97).

At the cellular level, the role of changes in the ADP/ATP ratio and the concentration of inorganic phosphate have received strong support (98,99) challenging the traditional view that accumulation of lactic acid and hydrogen ions is the main biochemical correlate of muscle fatigue. Others have highlighted the importance of cation pumps such as the Na<sup>+</sup>/K<sup>+</sup> ATPase (100) and the Ca<sup>+</sup> ATPase (101) in maintaining muscle excitability and preventing muscle fatigue. Cellular factors may also play a role in muscle fatigue in disorders of the central nervous system such as multiple sclerosis and amyotrophic lateral sclerosis (102,103). It is likely that multiple mechanisms interact under various conditions, resulting in the clinical phenomenon called muscle fatigue.

### Absolute and Relative Endurance

One simple test of dynamic endurance is to count the number of repetitions that a subject/patient can do with a given load. Similarly, a test of static endurance could measure the length of time that a given level of force can be maintained. Since both tests use an absolute load or level of force, stronger subjects/patients will be tested at a relatively lower percentage of their strength than weaker subjects. For example, a dynamic test conducted using a 40-kg load represents 40% and 80% of the strength of individuals with a 1 RM test of 100 and 50 kg, respectively. Tested at a lower percentage of his or her strength, the stronger individual will demonstrate better endurance.

To control for the effects of muscle and body size, a similar testing paradigm can be used, but based on a percentage of the individual’s strength. This relative endurance test requires the performance of as many repetitions as possible using, for example, 50% of the dynamic strength of the individual. It can also be done by asking the individual to maintain a relative level of static force for as long as possible. The relative endurance test limits the influence of body or muscle size on the measurement and may allow for a better way to compare different groups of patients.

### Fatigue Indices

Isokinetic devices have been used to quantify muscle fatigue and endurance by measuring relative losses in peak torque and/or work during a standardized test. For example, the

ratio between peak torque or work performed during the first and last three or five repetitions of a series of repetitions, usually 25 to 100, depending on the muscle group under study, has been used as an index of muscle fatigue. Since the calculation of work performed is based on the integration of the area under the curve, it is important to make sure that, during the test, the joint moves through the entire predetermined range of motion. Studies that have measured both fatigue and strength reproducibility using isokinetic dynamometers have found that fatigue tests are less reliable than strength tests (104–106). In a study of the reliability of an isokinetic fatigue test for concentric ankle dorsiflexion, it was shown that fatigue indices using decreases in peak torque were more reliable than an index based on relative decreases in work, but that all indices showed acceptable to good reliability (107).

A similar approach has been used by other investigators, but during static muscle actions. A combination of the percent reduction in force over a given period of time and the average augmentation with electrical stimulation superimposed during contractions has been proposed as a clinically useful method of quantifying muscle fatigue (108).

### Spectral Analysis of the Surface Electromyographic Signal

Spectral analysis of the surface electromyographic signal is based on the idea that, during the performance of static muscle actions, a reduction of the median frequency correlates with the drop in force and therefore is an indirect indicator of muscle fatigue (109). The median frequency reflects muscle fiber conduction velocity and motor unit recruitment and therefore is influenced by the fiber type composition of the muscle. Some authors have proposed that a shift in the mean power frequency of the EMG is actually a selective indicator of fatigue of the fast-twitch motor units (109) and that subjects with higher concentrations of fibers expressing type II myosin heavy chain isoform displayed greater reductions in median frequency of EMG and muscle fiber conduction velocity during exercise (110).

Another approach based on the study of changes in the EMG signal during voluntary contractions has been proposed by Merletti and Roy (111). They studied the rate of spectral compression of the surface EMG signal during the early phases of static voluntary muscle actions of the tibialis anterior. The slope of the median frequency during the first 30 seconds correlated with endurance time. The authors proposed the use of this technique in the clinical setting in part because the test does not require the use of muscle actions to failure.

### Nuclear Magnetic Resonance

Nuclear magnetic resonance (NMR) is used to study the metabolic correlates of muscle fatigue at rest and during exercise (Fig. 3-9). Changes in intracellular pH, concentrations of inorganic phosphate, phosphocreatine (PCr), ADP, and ATP

**FIGURE 3-9.** NMR spectra from the calf muscles of a sprint athlete at rest and during 5 minutes of progressive exercise. Note the reduction in phosphocreatine (PCr) and the accumulation of inorganic phosphate (Pi) with progression of exercise. Also, note the relative conservation of adenosine triphosphate (ATP), which protects the muscle cell from permanent damage (112).

resulting from the metabolic demands imposed on active muscles can be monitored in real time at rest, during exercise and fatiguing conditions, and during the recovery period (112). The speed at which a muscle recovers from these metabolic alterations is a good indicator of the fitness level of the individual. An interesting point is that the accumulation of these metabolites alters the conduction of the action potential and explains the changes in the spectral content of the EMG signal mentioned earlier. This technique has the advantage of being noninvasive. However, it is expensive and not readily available in the clinical setting.

### Other Tests of Muscle Properties Related to Fatigue and Endurance

#### Near Infrared Spectroscopy and Microdialysis

Near infrared spectroscopy (NIRS) is a relatively new, noninvasive research instrument to measure oxygen ( $O_2$ ) through tissues up to 10 cm in depth (113). NIRS can be used to investigate the delivery and utilization of oxygen in response to exercise and in the clinical setting to assess circulatory and metabolic abnormalities (114). Quantitative measures of blood flow are also possible using NIRS.

Microdialysis is an invasive research technique that has allowed mechanistic investigations to be performed in human skeletal muscle. The microdialysis catheter has been equated to an artificial blood vessel, which is introduced into the tissue. By means of this “vessel,” the concentrations of compounds in the interstitial space of skeletal muscle (as well as other tissues) can be monitored. A number of important observations on the *in vivo* regulation of lipolysis, carbohydrate metabolism, and blood flow in human skeletal muscle and adipose tissue have been made using microdialysis (115).

## STRUCTURAL CHARACTERISTICS OF SKELETAL MUSCLE

### The Relationship Between Function and Structure

The relationship between the structure and the function of biological systems has received significant scientific attention. Ewald Weibel, the great Swiss morphologist, concluded in his book on the structure and function of the mammalian respiratory system that, “I have become convinced not only that structure determines function, but that functional demand also determines structural design, be it through evolution or by modulation of design features” (116). The importance of function as a determinant of form has also been emphasized by Russell et al. (117). In their review, they demonstrated how the functional demands imposed on muscle cells result in adaptations in muscle cell shape, size, and force production.

Based on the previous paragraph, a discussion about muscle function cannot be comprehensive unless some of the structural and architectural features of skeletal muscle are analyzed. The level of force and power generated by an active muscle is influenced by muscle size, fiber angle of insertion, and sarcomere length (118,119). Muscle length contributes to shortening velocity, and muscle fiber type composition is an important determinant of speed and endurance. We will now discuss some of the measurements of muscle structure that are used in rehabilitation clinics and research laboratories.

### Body Composition: Estimating and Measuring Muscle Mass in Humans

The human body is composed of various types of tissues (including skeletal muscle) with different chemical consistency. The study of body composition allows a determination of the amount and anatomic quality of these components. Body composition is associated with health status and functional capacity, among other outcomes. The study of body composition can be accomplished using different compartment models (Fig. 3-10) (120). Skeletal muscle and its constituents, although sometimes measured indirectly, are important components in each of these models. The chemical composition of muscle has been described as approximately 75% water and 20% protein, with the remaining 5% made up of inorganic salts and other substances that include high-energy phosphates, urea, lactic acid, calcium, magnesium, phosphorus, enzymes, potassium, sodium, chloride, amino acids, fats, and carbohydrates (121).

The traditional gold standard in the study of human body composition, hydrodensitometry or underwater weighing, and the more recent air displacement (plethysmography) are based on a two-compartment model. This model divides the body into fat mass (FM) and fat-free mass (FFM). In this context, the use of the term *fat-free mass* is thought not to be very accurate, since the nonfat component includes a small percentage of essential fat stores within the central nervous

**FIGURE 3-10.** Multiple compartment models for the study of human body composition. Note the relative contribution of skeletal muscle and its atomic, molecular, and cellular components in each of the models (120).

system, bone marrow, and internal organs. Thus, LBM is a more appropriate designation. LBM includes essential fat, muscle, and bone. Hydrodensitometry estimates body density (122), which is then used to calculate FM with the Siri equation, assuming a constant density for FM and LBM (123):

$$\text{Percent body fat} = \frac{495}{\text{density}} - 450$$

where density = mass (in air)/loss of mass in water (or mass in air mass in water). Accurate determination of density requires correction for water temperature. Finally, LBM is obtained by subtracting FM from the total body mass.

Elements at the atomic level can be quantified using neutron activation techniques (124,125). This is relevant to our topic of discussion because, as mentioned earlier, muscle is an important source of nitrogen. In addition, most of the potassium present in the body is intracellular, and a large amount is present in myofibers. The use of whole-body counters, special instruments capable of detecting radiation from the decay of the naturally occurring radioactive isotope of potassium, allows quantification of cell body mass and, indirectly, lean body and muscle mass (124,125).

Techniques such as dual-energy x-ray absorptiometry (DEXA) are used to quantify bone, fat (both subcutaneous and visceral) mass, and skeletal muscle mass (126,127). Total body and appendicular estimates can be obtained (126) at a lower cost and radiation exposure than with computerized tomography (CT). The most accurate *in vivo* methods of measuring muscle mass and segmental body composition are imaging techniques such as CT and magnetic resonance imaging (MRI) (see later).

## Muscle Size

A reasonable, but not always accurate, estimate of muscle size at a given limb level can be obtained in the clinic by measuring limb circumference with a metric tape. However, these measurements include fat, bone, and other noncontractile tissues. Furthermore, such measurements cannot be corrected for changes in limb circumference related to fluid shifts or tissue edema. In pathologic conditions where muscle is replaced by connective tissue and/or fat, such as in certain myopathic conditions, measurements of limb circumference can be very misleading.

Reliable estimates of muscle cross-sectional area can be obtained with modern techniques such as ultrasound (128,129), CT (130), or MRI (130–132). Ultrasound has been used extensively because of its simplicity, its low cost, and the fact that it does not involve exposure to radiation. However, it does not provide an optimal distinction of the borders between the various tissues. Another application for ultrasound techniques has been the *in vivo* study of the architecture of the muscle tendon complex (133). Measurements of tendon length, muscle fascicle length, pennation angle of muscle fibers, tendon elongation during muscle contraction, tendon strain, and related properties have been done *in vivo* in humans. These measurements can help us understand muscle function. For example, because muscle fibers consist of sarcomeres in series, the muscle fiber length indicates the velocity potential of a muscle during contraction. The longer fascicles in the vastus lateralis muscle result in faster velocity than that occurs with the medial gastrocnemius. However, the tendon of the medial gastrocnemius has a higher compliance and therefore a greater potential to store elastic energy (134).

Both CT and MRI have been widely used to obtain valid (using cadaver measurements as the standard) and reliable measurements of total thigh, muscle, subcutaneous fat, and bone cross-sectional areas in health and disease (130,135). In both CT- and MRI-based methodologies, anatomic cross-sectional area refers to the area measured from a single cross section of the muscle. The measurement is made perpendicular to the long axis of the muscle. Because in pennate muscles like the quadriceps femoris fibers do not run parallel to the longitudinal axis of the muscle, these measurements underestimate the true muscle area (136; Fig. 3-11). On the other hand, if measurements of muscle volume obtained by MRI are combined with estimates of muscle fiber length from cadavers, physiologic cross-sectional area can be calculated with reasonable accuracy (137,138).

Both CT and MRI have been shown to provide valid estimates of muscle cross-sectional area (130). The higher definition MRI provides better area estimates than CT images. The latter tends to systematically overestimate anatomic cross-sectional area by 10% to 20% (139). Both MRI and CT have been shown to have high intrarater and interrater reliability and are capable of detecting exercise-training induced adaptations in skeletal muscle (74,140,141).

**FIGURE 3-11.** The influence of pennation angle on the thickness of muscle and estimations of muscle size. CSA, anatomic cross-sectional area; PCSA, physiologic cross-sectional area. These two muscles have the same number of fibers of the same thickness. By increasing the pennation angle  $\alpha$ , thickness of the muscle (CSA) belly decreases. The pennation angle allows more of the muscle mass to be closer to the joint, reducing the resistance to movement (136).

T1-weighted MRI allows muscle tissue and noncontractile tissue components (connective tissue, subcutaneous and interstitial adipose tissue) to be separated (130,140). Cross-sectional images of the human thigh and leg obtained using MRI are presented in Figure 3-12 (132). Computer-based image analysis systems can be used to quantify the composition of muscle, fat, and connective tissue by assigning different density values to the different tissue components. Muscle attenuation, a function of tissue density and chemical composition, has been shown to relate to its lipid content (141). Furthermore, since disease and exercise training may alter both the contractile and noncontractile components of the limb, it is very useful to be able to quantify changes in these two compartments (140).

MRI has also been used to assess the level of activation of different muscles or parts of muscles during volitional exercise and neuromuscular electrical stimulation (142,143). MRI can provide a noninvasive way to quantitatively evaluate and localize muscle activity. The underlying mechanism that explains this phenomenon is the accumulation of osmolites (phosphate, lactate, sodium) in the cytoplasm during exercise, resulting in the influx of fluid and an increase in muscle T2 relaxation. A practical application of this technique is the use of the T2 relaxation times to evaluate muscle activation during specific exercises. (For a detailed discussion of radiologic techniques, see Chapter 6.) For example, a recent study demonstrated that both the “empty can” and the “full can” exercises activate the

**FIGURE 3-12.** Cross-sectional images of the human thigh (**A**) and leg (**B**) obtained with MRI and a schematic drawing of the muscles of the leg. Note the clear difference in density of the muscle (contractile) and fat and connective (noncontractile) tissues (132).

supraspinatus muscle to a larger extent than the horizontal abduction exercise (144). This information could be used to design the optimal combination of exercises for strengthening rehabilitation programs. Thus, only those exercises that activate a large proportion of the injured or weak muscles are included in the rehabilitation program.

When comparing different patient populations, subjects with different levels of physical fitness, or measurements done before and after exercise training, we must take into account the fact that force varies with size (Fig. 3-13) and that larger individuals will be stronger if absolute strength is used as an outcome. These comparisons should only be made after strength is adjusted for differences in muscle physiologic cross-sectional area or volume or for the amount of noncontractile tissue components. The ratio between force generated and measurements of muscle area is known as specific force and has been used as an index of “muscle quality” (138,145–147). A simple ratio, however, may not be the best way of adjusting muscle strength, and more sophisticated statistical treatment may be needed (148–150).

### Muscle Biopsy Techniques

Despite recent advances in noninvasive muscle-imaging techniques, analysis of small samples of human skeletal muscle

is still the only way to determine various changes in the fiber population as a result of an intervention or to investigate the underlying pathophysiologic mechanisms of muscle

**FIGURE 3-13.** Relationship between muscle strength and size in humans. Note that the correlation is not 1, suggesting that factors other than muscle size (e.g., motor unit activation, fiber type distribution, muscle fiber quality) explain a significant percentage of the variability in muscle strength among subjects or patients.

dysfunction. Muscle biopsies for various morphologic and biochemical studies can be obtained with the open and percutaneous (needle or semiopen conchotome) biopsy techniques (Fig. 3-14). The needle biopsy technique was introduced by Duchenne in 1868 (151) and has been successfully adapted or modified by others (152–156) for the study of neuromuscular and systemic diseases affecting skeletal muscle (157–159), adaptations to exercise training (160–162), and aging (163). An alternative technique is the semiopen conchotome technique (155,164), which usually yields larger samples than the needle technique. With either technique, the procedure is done under local anesthesia and is usually well tolerated by research subjects and patients. Ultrasound (165,166) and MRI (167) have been used to guide the placement of the biopsy needle to the area of interest in the muscle under study. The skeletal muscles most frequently biopsied are the vastus lateralis, lateral gastrocnemius, triceps surae, tibialis anterior, and biceps brachii.

It must be noted that a biopsy sample represents a very small fraction of all the fibers in a large muscle such as the vastus lateralis. A biopsy sample from this muscle may contain several hundred to a few thousand fibers, compared with hundreds of thousands in the whole muscle. Thus, because there is significant intramuscular variability in the distribution of fiber types, more than one sample may be needed to

obtain a good estimate of the fiber type proportion (168). The determination of fiber size and capillarity, however, appears to be less problematic. It has been suggested that one biopsy sample may suffice (169–171), although several small samples are advantageous when muscle fiber areas are determined (172).

### Muscle Fiber Size and Type Distribution

Histologic and histochemical techniques have been used for more than half a century to study muscle cross sections under light microscopy (173,174). Over the last decades, immunocytochemical techniques have been introduced. These techniques use chemical reagents (stains) that react with components of the muscle fiber, allowing the visualization and assessment of various structural and functional muscle characteristics such as fiber size and shape, fiber type distribution, capillary supply, enzyme activity, nuclei distribution, satellite cells, intracellular carbohydrates and lipid stores, amount of intercellular connective tissue, degree of fat infiltration, presence of intracellular structures such as inclusion bodies, and others.

Table 3-3 summarizes the most common staining procedures of human muscle biopsies. Many of these techniques are used as part of the clinical investigation of muscle biopsies (e.g., to diagnose a specific neuromuscular disorder). Other procedures are used to investigate pathologic changes in general, and yet others are only used for research.

Muscle biopsy cross sections can be stained with hematoxylin and eosin for the evaluation of the general morphology of muscle fibers, including its size, shape, and location of nuclei. The identification of capillaries in the muscle biopsy cross section can be accomplished with the periodic acid-Schiff amylase stain or immunocytochemical procedures with antibodies against laminin or ulex europaeus agglutinin I (UEA) lectin (175). This is an important property of skeletal muscle, given the fact that capillarity changes significantly with exercise training, disease (e.g., peripheral vascular disease), and immobilization. A qualitative assessment of various oxidative and glycolytic enzymes can be done with specific enzymatic stains such as succinate dehydrogenase (SDH), NADH tetrazolium reductase (NADH-TR),  $\alpha$ -glycerophosphate dehydrogenase (GPDH), cytochrome C oxidase (COX), and phosphofructokinase (PFK). Finally, qualitative and quantitative estimates of lipid and carbohydrate content are possible via histochemical and biochemical methods. The glycogen depletion technique has been used for several decades to identify the pattern of activation of motor units in various types of exercises; the reader is referred to other publications on this subject for more details (176).

The mATPase stain is one of the most widely used to visualize the fiber population and evaluate changes in the size and proportion of the different fiber types following an intervention such as detraining (Fig. 3-15). Based on the mATPase activity, the human muscle fiber population is commonly classified into types I, IIA, IIB, and IIC (177). This original mATPase-based semiquantitative classification of muscle fibers has been expanded, and seven different human muscle fiber types are now being identified: I, IC, IIC, IIAC, IIA, IIAB,

**FIGURE 3-14.** The needle muscle biopsy technique. This technique can be used to obtain muscle samples for research studies and for clinical diagnosis. The application of suction enhances the amount of tissue obtained for analysis (157).

TABLE 3.3

Examples of Staining Procedures of Human Muscle Biopsies

Histologic stains	
Hematoxylin & eosin (H&E)	Stains nuclei and cytoplasm, used to assess general structure, location of nuclei, inflammation, regeneration
Periodic acid-Shiff (PAS)	Glycogen, shows abnormal accumulations of glycogen and related metabolic disorders
Oil red O or Sudan black	Lipid droplets
Modified Gomori trichrome	Stains mitochondria, nuclei, used to visualize ragged red fibers with excess mitochondria
Histochemical stains	
Myosin ATPase at pH 4.3, 4.6, and 9.4	Used to visualize and differentiate muscle fiber types
Oxidative enzymes	
NADH	Stains intermyofibrillar material such as mitochondria, sarcoplasmic reticulum, t tubules, target fibers
SDH	Stains mitochondria (complex II, encoded entirely in nuclear DNA), visualizes subsarcolemmal and intermyofibrillar distribution, indicates excess mitochondrial activity
COX	Stains mitochondria (complex IV), used to detect mitochondrial myopathies that lack the enzyme
Other enzymes	
PFK	This enzyme is active in the glycolysis and absent in type VII glycogenosis
Myophosphorylase	Indicates excess of glycolytic activity or absence, as in McArdle's disease (type V glycogenosis)
Immunocytochemical stains	
UEA	Stains capillaries
Dystrophin	Duchenne and Becker muscular dystrophy
Desmin and vimentin	Cytoskeletal proteins, used to visualize congenital myopathies and myopathies with cytoplasmic bodies
Lymphocyte markers	Used to visualize mononuclear inflammatory cells
N-CAM	Used to visualize regenerating and denervated fibers

and IIB (178,179). Perrie and Bumford (180) refined the electrophoretic techniques and separated the human myosin heavy chains (MHC) into three isoforms: I, IIa, and IIx, which have been shown to correlate with the three major mATPase-based fiber types (181–183). It is now known that the mATPase-based type IIB fibers correspond to MHC IIx identified by gel electrophoresis (184,185). Studies of single muscle fibers have

also shown that fibers can contain a mixture of MHC isoforms. The mATPase types IC, IIC, and IIAC coexpress the MHC I and IIa to a varying degree, whereas type IIAB fibers coexpress MHC IIa and IIb/x (179). As the enzyme histochemical and electrophoretic techniques can yield different information, it is recommended that both techniques are used when the muscle fiber type population is quantified (186).

**FIGURE 3-15.** Microscopic image of a muscle biopsy from the human tibialis anterior muscle visualizing type I (lightly stained) and type II (heavily stained) fibers.

### STUDIES OF SINGLE MUSCLE FIBERS

The percutaneous biopsy technique has been used to obtain muscle fiber segments for the study of the morphologic, contractile, and biochemical properties of single human skeletal muscle fibers (187,188). These single fibers are permeabilized with high glycerol concentrations and a detergent solution, resulting in breaks in the sarcolemma and the sarcoplasmic reticulum. The absence of these barriers permits the rapid diffusion of calcium into the cell and its interaction with troponin C, triggering the cascade of events that lead to force generation. Before these experiments are done, the fibers are attached to a force transducer that measures force generation during activation and a servomotor that controls the sarcomere length (Fig. 3-16). An image analysis system is used to measure sarcomere length, muscle fiber length, diameter, and depth; the latter two are used to calculate fiber cross-sectional area.

Measurements of maximal static force, peak power, and shortening velocity are obtained by activating the fiber with calcium (150,189). Using a different experimental protocol, the force-velocity and force-power relationships of the single fibers

**FIGURE 3-16.** Light microscopy image of a human single muscle fiber. The fiber is attached to a force transducer and a lever system to control its length. Notice the well-preserved striation pattern.

can also be studied. When contractility studies are completed, the fiber segment is submitted to protein gel electrophoresis to determine the expression of myosin heavy chain isoforms and thereby the fiber type (Fig. 3-17). This electrophoretic technique has the advantage over the APTase stain of allowing the identification of hybrid fibers, fibers expressing simultaneously two or more myosin heavy chain isoforms.

The single muscle fiber method complements the techniques used to measure *in vivo* muscle function by making it possible to study the contractile behavior of single fibers in the absence of confounding variables such as the influence of the nervous system, the presence of intercellular connective tissue, the heterogeneity of muscle fiber type distribution,

**FIGURE 3-17.** Protein gel electrophoresis (SDS-PAGE) of human skeletal muscle single fibers for fiber type identification. One muscle fiber per lane. Most fibers express one myosin heavy chain isoform (bands). Notice also the hybrid fibers simultaneously expressing more than one myosin heavy chain isoform (i.e., third lane from right).

and the connectivity to the tendon-bone interface. Adjusting measurements of contractility for differences in muscle fiber size has been used as an index of muscle fiber quality.

## FUNCTIONAL TESTS OF MUSCLE PERFORMANCE

In a clinical setting, it is sometimes not practical or efficient to evaluate muscle function with expensive devices and time-consuming laboratory-based tests. Furthermore, in research and patient care, there is a need to measure performance in tasks that are more similar to activities of daily living (ADLs) and instrumental activities of daily living (IADLs) than many sophisticated laboratory tests. These two considerations have resulted in the development of simple, inexpensive, and easy-to-administer tests of neuromuscular function or performance. These measurements do not represent direct evaluations of skeletal muscle or any other isolated physiologic characteristic but rather an integrated response of the human body to the demands of a particular task. However, muscle strength and power correlate well with test performance scores. These tests are described in various publications together with normative data (20,190,191), and some of them will be described later.

### Chair Stand Time

In general, the chair stand time test (190,191) requires a chair with arms and a seat placed against a wall for support and safety. Subjects should sit all the way back in the chair with their back against the back of the chair. The feet should be placed so that the knee is in a 90-degree angle. The patient or research subject is instructed to stand up and sit back down as fast as possible for five or ten repetitions with the arms crossed at the chest. Time is measured with a stopwatch to the nearest 0.01 second and stopped after the last stand. The subjects should come to a complete stand each time and completely sit down with their backs against the back of the chair each time. This test can be considered an indirect index of knee extensor function, since this muscle group produces 72% of the power needed to rise from a chair (15).

### Stair-Climbing Power

A standard stair flight with handrails on each side is used for the stair-climbing test (192). Subjects are instructed to ascend stairs as quickly as possible using the handrail and/or an assistive device if necessary. The test is started with both of the subject's feet on the bottom step. The subject is instructed to climb up the steps as quickly as possible. A stopwatch is used and stopped when both feet are planted at the top step. Time is recorded to the nearest 0.01 second, and the best of two trials (separated by a 2-minute rest period) is taken. Power, in watts, is calculated using the following equation:

$$\frac{\text{body weight (kg)} \times \text{vertical distance (m)}}{\text{time (s)} \div 60} \div 6.12$$

(Note that 6.12 kg-m/min = 1 watt.)

### Habitual and Maximal Walking Speed

Walking speed correlates with strength of the ankle dorsiflexors and knee extensors (10,193–195) and leg extension power (195). This relationship has been shown to be nonlinear (10,196). In other words, the decline in gait time with increases in strength is curvilinear, and there is a threshold value below which the relationship is lost. In longitudinal studies, baseline strength of the knee extensors has been shown to be a good predictor of 2- and 4-year decline in walking velocity (193). Walking speed is also correlated with isokinetic knee extensor and flexor torque in chronic stroke patients; strength for the paretic limb explains up to 50% of the variance in gait performance (197).

Walking velocities can be measured to the nearest 0.01 second as the mean of two trials using a stopwatch and a set distance or a gait speed monitor. The subject or patient will start the test with feet parallel and both heels and toes on the floor. For the habitual walking speed test, patients or subjects are instructed to walk at their normal or comfortable speed. During the maximal walking speed test, they are required to walk as quickly as possible. Velocity is recorded after subjects walked a given distance to control for individual differences in acceleration. Measurements of walking speed have been shown to be highly reliable in a number of patient groups (198).

### The 6-Minute Walk Test

The 6-minute walk test requires that subjects walk for 6 minutes covering as much ground as possible at a pace that would allow them to talk without becoming short of breath (199). The test may be conducted in a circular track or on a level course. The subject is allowed to rest but instructed to continue walking if possible. The tester times the walk with a stopwatch. After 6 minutes, the distance walked is measured.

Although sometimes considered a test of aerobic capacity, endurance, and survival in patients with heart disease (200), it has been shown that performance in the 6-minute walk test correlates with lower-extremity muscle strength and power (197, 201). Performance in this test depends on multiple physiologic, psychologic, and health factors (202). Muscle strength, balance, medication use, and age explain the largest proportion of the variance in the performance of this test.

## MUSCLE FUNCTION, EXERCISE TRAINING, AND FUNCTIONAL PERFORMANCE

In this chapter, we have emphasized that muscle function is related to performance. In rehabilitation, improvements of physiologic capacity are only relevant if these improvements have functional consequences, reduce disability, and increase participation. However, the association between muscle function and functional performance is not necessarily linear (203) (Fig. 3-18). In the presence of disease but a high degree of muscle function, exercise could serve as a means of preventing the deleterious consequences of disease progression and inactivity.

**FIGURE 3-18.** The nonlinear relationship between muscle function (e.g., muscle strength) and functional performance (e.g., walking ability) and the differential effects of exercise on functional performance, depending on the degree of disease progression (203).

When chronic illness has resulted in severe functional losses, exercise training may be used as a form of recreation. In the steep part of the curve, a relatively small loss of muscle function could result in disproportionate reduction in performance. Thus, even minor adaptations to exercise training could preserve functional capacity and independence. The minimal level of muscle function needed to achieve this goal remains to be determined.

## CONCLUSION

Understanding the role of skeletal muscle in health and disease is of paramount importance for those interested in rehabilitation medicine. A wide range of techniques and methods have been developed to assess muscle function and structure. Becoming proficient in their applicability and use is relevant to patient care, education, and research in physical medicine and rehabilitation.

# Electrodiagnostic Evaluation of the Peripheral Nervous System

## INTRODUCTION

The ability to perform high quality electrodiagnostic studies is a critical skill for the practicing physiatrist. Electrodiagnosis is an important and helpful extension of the physical examination and can detect minor abnormalities when physical examination cannot. Moreover, the electrodiagnostic examination has several other key functions in the assessment of peripheral nervous system injuries. These techniques provide insight into the pathophysiology of a nerve lesion (such as demyelination or axon loss). By quantifying the degree of axon loss, one can estimate prognosis for recovery of lower motor neuron lesions. Finally, electrodiagnostic methods enable one to quantitatively track disease processes and complement the qualitative estimates afforded by the clinical examination.

## PREPARING FOR THE ELECTRODIAGNOSTIC EXAMINATION

The electrodiagnostic examination needs to be interpreted in the context of the clinical presentation. Simply performing nerve conduction studies or needle electromyography (EMG) without understanding the patient's presentation or developing a differential diagnosis does a disservice to the patient, as the diagnosis will often be incomplete or incorrect.

For these reasons, there are several key steps to prepare for the electrodiagnostic examination, including review of referral materials, eliciting the patient's history, performing a directed physical examination, developing a differential diagnosis, and putting together a plan for the electrodiagnostic evaluation.

*Review of referral materials:* It is critical that the electrodiagnostic consultant starts by reviewing the question from the referring physician so that he or she knows what is being asked for. Without reviewing this information first, it is easy to be misled into another diagnostic pathway and never answer the referring physician's question. If there is any uncertainty about what is being asked for, it is often helpful to talk to the referring physician. If it is not possible to address the question being asked by the electrodiagnostic examination, one should have that discussion with the referring physician before starting the electrodiagnostic study.

*Patient history:* A focused patient history is very important to allow one to establish a differential diagnosis before heading into the physical examination and then the electrodiagnostic evaluation. The history should start off with the chief complaint, but should also include exacerbating or relieving factors and past medical history. It is often useful to ask what medications the patient is taking so that one is not later surprised by easy bleeding (in the setting of warfarin usage) or by a polyneuropathy (e.g., diabetes). Parts of the past medical history may be especially contributory to the differential diagnosis such as diabetes, history of cancer, or toxic exposures. When one starts to consider diseases that may be hereditary, it is always wise to ask about any family history of neuromuscular problems.

The *physical examination* needs to be focused and adapted to the individual presentation of the patient. Typically, it is useful to assess muscle strength not only in the involved body part but also in bilateral upper and lower limbs. One will want to detect even subtle weakness in the patient before starting the study. Since most patients coming to the EMG laboratory will have at least 4/5 strength, it is usually not possible to fully test the ankle plantarflexors or dorsiflexors by manual muscle testing. It is much more effective to have the patient walk on his or her heels and toes and do other functional tests as appropriate (e.g., squatting).

One should get a rough sense of the distribution of sensory loss. Two techniques are particularly helpful in this regard. First, in mild sensory loss, it is often helpful to compare with an area of normal sensation and ask, "If this is 100 (testing normal area), how much is this (testing abnormal area)?" Generally, losses of small percentages are not important. Secondly, if an area of abnormal or absent sensation is clearly established, it is useful to map this out, putting small pen marks where sensation changes from abnormal to normal. When discussing the distribution of sensory loss, it is better to describe it in anatomical terms (e.g., small finger) rather than in root or nerve distribution terms, since one often does not know whether sensory losses are in a peripheral nerve, plexus, root, or other distribution (e.g., ulnar nerve, medial cord, lower trunk, C8 root or spinal cord).

Muscle stretch reflexes are one of the few objective indicators of nerve or muscle disease. Hyperreflexia usually suggests an upper motor neuron etiology, while diminished reflexes or areflexia are more consistent with a peripheral nerve or lower motor neuron process.

Provocative signs can be somewhat helpful but have limited diagnostic accuracy. One may consider Spurling's sign for cervical radiculopathy, straight leg raise sign for lumbar radiculopathy, Tinel's, Phalen's, or flick sign for carpal tunnel syndrome, and other maneuvers. Generally, these provocative signs have a limited specificity (1).

In many settings, where an electronic medical record is present, it is possible to briefly review radiologic findings and other laboratory data before establishing the differential diagnosis. This can be helpful to either expand or appropriately contract the differential diagnosis as needed. One should keep in mind, however, that there will not always be a good correlation between imaging studies and electrodiagnostic findings.

After completing the clinical assessment above (which should usually take no more than 15 to 20 minutes), one should establish the differential diagnosis. This important step is often skipped and can result in overlooking important possible diagnoses or missing significant tests. The examining physician should ideally write down his or her differential diagnosis. One can consider the differential diagnosis starting from most likely to least likely or starting centrally in the nervous system and work peripherally so that important possibilities are not overlooked. It is generally wise to include the diagnosis the referring physician has suggested on your list, since you want to be able to answer his or her question in your final report.

After the differential diagnoses have been articulated, one can then establish a plan for diagnostic testing. One should

look at the differential diagnoses and decide what elements of electrodiagnostic study are needed to assess for those possible diagnoses. One may elect to modify this plan as initial information is attained, and in fact, this is often an iterative process. However, without going through the rigor of developing (and writing down) a plan based on the differential diagnosis, one will miss important findings (Fig. 4-1).

## TYPES OF ELECTRODIAGNOSTIC TESTING

Although there are many techniques that can be employed in electrodiagnostic assessment, this chapter will cover the primary techniques including nerve action potentials (sensory and mixed), motor nerve conduction studies, late responses (F waves, H waves, and A waves), needle EMG, and repetitive stimulation. For each technique, this chapter will discuss the physiology, normal findings, applications, abnormalities, limitations, and the likely encountered sources of error.

### Sensory Nerve Action Potentials and Compound Nerve Action Potentials

Sensory nerve action potentials (SNAPs) and compound nerve action potentials (CNAPs) both involve electrical stimulation of nerves and recording of the synchronized discharge of axons within the nerve at some distance from the point of stimulation. SNAPs are responses that only involve sensory axons, whereas CNAPs may involve sensory axons, motor axons, or a mixture of both.

The nerve is stimulated supramaximally, meaning that all the axons are electrically stimulated. In practice, this means that stimulator intensity (mA) is gradually increased while monitoring the size of the nerve response. When the response from the nerve gets no larger as the intensity continues to increase, this indicates that all the available axons have been activated and further increases in stimulation will activate no more axons. One should be aware, however, that increasing the stimulator substantially above this level will sometimes activate other nearby nerves, and responses from these other nerves can be recorded from the same recording electrodes (Fig. 4-2) through volume conduction; this is to be avoided.

**FIGURE 4-1.** Steps in the evaluation of a patient referred for an electrodiagnostic medicine consultation.

**FIGURE 4-2.** Amplitude of CMAP or SNAP as current is increased. Note that with very high levels of stimulation, amplitude will increase above supramaximal due to co-stimulation of nearby nerves.

FIGURE 4-3. Example of an SNAP.

One records from the same nerve at a specified or measured distance away from the stimulation and records the synchronized discharge of all the axons that have been activated (Fig. 4-3).

Several items are then measured from the nerve action potential. Most commonly, these include the latency and amplitude of the response. The latency can either be measured to the onset of the response or the peak. The advantage of measuring to the onset is that this represents the fastest conducted fibers, and it also depends less on the distance between active and reference electrodes. The advantage of measuring latency to the peak is that the peak is more reliably determined and less influenced by the sensitivity of the display or the amplifier. In either case, one should have reference (normal) data, which have been derived using the same technique. The amplitude or size of the response can be measured from baseline to peak or from peak to peak, again depending upon how the reference data were collected. Conduction velocity is in units of distance over time, in this case meters per second (m/s), which is the same as millimeters per millisecond (mm/ms). In the case of nerve action potentials, one can measure the distance between stimulation and recording and divide that by onset latency to obtain the velocity in meters per second.

Conceptually, one should consider what factors will influence the latency (or conduction velocity) and amplitude of sensory responses. The latency can be affected by a number of both physiologic and pathologic processes. Cold slows conduction velocity. This effect varies from nerve to nerve but generally is in the range of about 5% per °C. Conduction velocity also changes with age. Initially, children are born with conduction velocities about half of that of adults. As their nerves become more myelinated, these values approach normal values around age 3. Later, in the fifth and sixth decades, velocities start to slow again but not to the degree of that seen in infancy. For this reason, reference values are often adjusted for age.

With respect to pathological changes, loss of myelin will cause slowing of conduction velocity and increase in latencies. When demyelination becomes severe enough, however, conduction block will occur. One might think that such fibers could conduct slowly, as unmyelinated fibers do. However, since myelinated fibers do not typically have sodium channels underneath the areas of myelin, in the setting of intense demyelination, they cannot conduct as unmyelinated fibers do and so conduction is blocked.

The amplitude of the response is also affected by temperature. Cold tends to increase the amplitude of the response if the recording electrodes are over a cold area of the limb. This increase in size is because cold slows both the opening and, even more, the closing of sodium channels. As a result, more charge is exchanged across the axon plasma membrane and a greater size axon potential is elicited. This increased potential is then summated across many axons and the nerve action potential becomes enlarged. Amplitude is also dependent upon the distance of the electrodes from the generator source. The electrical potential amplitude falls off rapidly with distance as one moves further from the nerve. Thus, nerve conduction studies in which the response is close to the skin (such as recording from the fingers) usually generate a bigger amplitude response than when one is recording from proximal areas of the limb (where the nerves are located deeper).

Amplitude of the SNAP or CNAP can be thought of as representing the number of axons that are participating in the response. As one loses axons, the amplitude falls roughly in proportion to the degree of axon loss. In some cases, a reduction in amplitude can result from axon loss occurring between the stimulating and recording electrodes, in which case changes in the potentials would be seen immediately. However, SNAP amplitudes will also be reduced if sensory axons are affected anywhere from their cell bodies (which are located in the dorsal root ganglion or DRG) distally. In such cases, the axons undergo wallerian degeneration, and by 10 days after a proximal loss of sensory neurons or axons, the distal response will disappear due to axonal degeneration. On the other hand, if lesions are proximal to the DRG, then the distal axons will remain connected to their cell bodies in the DRG and will conduct normally, even if the patient has complete anesthesia.

Sensory nerve conduction studies can be most useful in diagnosis of lesions that are distal to the DRG, including plexopathies, entrapment neuropathies, and polyneuropathies. Sensory nerve conduction studies should usually be normal in the setting of radiculopathies (when injury is typically proximal to the DRG), central nervous system disorders, neuromuscular junction (NMJ) diseases, and myopathies (the latter two because recordings are obtained from nerve and not muscle).

One should be aware of several potential limitations in utilizing SNAP or CNAP studies. First, these can be technically challenging to obtain when responses are small, such as in

people with polyneuropathies, people with thick or calloused skin, or in older individuals. It can be challenging as well in unusual nerves that are not commonly studied. Hence, in less frequently studied nerves, one should interpret the absence of a response with caution and consider studying the contralateral limb as well as other sensory nerves. Electronic averaging of responses can be useful to elicit small amplitude responses that would otherwise be unnoticeable in the baseline electronic noise.

As mentioned above, temperature will have significant impact on sensory nerve conduction studies. One should consider that the limb might be cold if latencies are prolonged but amplitudes are large. In contrast, with disease states, latencies would be prolonged but amplitudes would usually be small. If one is unsure about whether temperature is having an influential effect, it is best to warm the limb. This author puts the limb into a plastic bag and then submerges it in a “cooler” or sink filled with warm water for 5 minutes. There are many other techniques, including warm air (e.g., from a hair dryer), infrared lamps, and other methods.

### Compound Muscle Action Potentials and Motor Nerve Conduction Studies

Compound muscle action potentials (CMAPs) involve electrical stimulation of nerves and recording of the synchronized discharge of muscle fibers in the muscle supplied by the stimulated nerve.

As above, for sensory nerves, the nerve is stimulated supramaximally. As opposed to SNAP or CNAP, one now records not from axons but from muscle fibers at a specified or measured distance away from the stimulation, and records the synchronized discharge of all the muscle fibers that have been activated (Fig. 4-4).

As with SNAPs, several measurements are taken from the CMAP. The amplitude or size of the response is usually measured from baseline to peak. The latency is measured to the onset of the response. Conduction velocity is more complicated to calculate than for SNAPs. Because the latency includes not only conduction time along the nerve but also time for NMJ transmission (about 1 ms), one cannot simply divide the distance between stimulation and recording by the distal latency. Instead, we stimulate at two points along the nerve and take the difference in distance divided by the difference in latency to derive a conduction velocity (see Fig. 4-4).

The latency can be affected by the same factors as for SNAPs. Physiologically, cold and advancing age slow

conduction velocity. With respect to pathological changes, demyelination will cause slowing of conduction velocity or increase in latencies. When demyelination becomes severe, conduction slowing and block will become evident.

CMAP amplitude is dependent not only upon the number of axons that are participating in the response, but also on the integrity of the NMJ and the number and integrity of the muscle fibers supplied by the axons. So, while NMJ defects and myopathies will leave CNAPs and SNAPs unaffected, these lesions can produce a reduction in CMAP amplitude. The CMAP will fall roughly in proportion to the degree of motor axon loss (or, in the case of myopathies, muscle fiber loss). As opposed to the SNAP (where lesions anywhere from the DRG distally cause an amplitude reduction), a reduction in CMAP amplitude can result from lesions from the anterior horn cell (the motor neuron cell body) distally. By 7 days after a proximal loss of motor cell bodies or axons, the distal response will disappear due to axonal degeneration; this occurs earlier than for the SNAP due to earlier failure of the NMJ.

Motor nerve conduction studies can be most useful in diagnosis of lesions that affect the lower motor neuron or surrounding myelin. This includes significant spinal root lesions, plexopathies, entrapment neuropathies, and polyneuropathies.

### Late Responses

While the typical motor and sensory conduction studies mentioned above rely on conduction distally in the limbs, there are several responses, known as late responses, which depend upon conduction proximally in the peripheral nervous system and thus occur with longer latency.

The F wave was so named because it was originally discovered in the foot (2). Physiologically, F waves depend upon conduction proximally to the motor neuron cell body. Since axons conduct in both directions, when motor axons are activated distally in the limb, they conduct both proximally and distally. For most axons, the impulse travels proximally, past the axon hillock, into the motor neuron and ends. But for a small number (about 3% to 5%), the depolarization traverses through the dendritic tree and comes back through the axon hillock after it is no longer refractory (about 1 ms). As a result, a small late response will be recorded from the muscle after enough time for a round trip from the stimulus site, back to the spinal cord and then back to muscle (Fig. 4-5). The reference (normal) values in humans are about 32 ms in the upper limbs and 55 ms in the lower limbs (3).

**FIGURE 4-4.** Example of a median CMAP. Conduction velocity is calculated by dividing the distance between the two stimulation sites by the difference in latencies.

**FIGURE 4-5.** Examples of F waves from an upper limb (**left**) and a lower limb (**right**). Note the variability of the response. (Note also sensitivity is different on the left of the sweep than on the right.)

The technique is similar to motor conduction studies but has several important differences (4). The sweep speed needs to be slow enough to capture the F waves (50 ms analysis time in the upper limb and 100 ms in the lower limb). Since F waves are smaller than CMAPs, sensitivity needs to be sufficient to observe these responses (200 to 500  $\mu\text{V}/\text{div}$ ); some EMG instruments have split screens with the first part of the sweep (e.g., first 20 ms) at 2 to 5 mV/div to observe the CMAP and the later part of the sweep at 200 to 500  $\mu\text{V}/\text{div}$ . Conventional teaching is that the cathode should be placed proximally along the nerve with the anode distally to avoid proximal anodal block, but this probably makes little or no difference (5) as long as the cathode is placed at the same location. Conventional teaching is also that the stimulation should be supramaximal, but latencies are similar even with submaximal stimulation (6).

Since F waves are derived from different populations of motor neurons for each response, the latency and appearance vary with each stimulation. Thus, measuring latency is more complicated than for a CMAP or SNAP, where the latency is the same with each stimulation. Because of this variability, one must acquire multiple F waves (typically 10 to 20) and take measurements that consider this variability. Most commonly, one obtains either the minimal latency (the shortest latency of multiple responses) or the mean latency (the average latency). The minimal latency is easiest to measure and is most commonly used. However, the minimal latency will depend upon the number of responses obtained. As more responses are recorded, the chances of finding a shorter latency response increase and the minimal latency will drop. The mean latency, on the other hand, is more time-consuming to measure since

one must mark all the F-wave responses obtained. But mean values are less dependent upon sample size, and the measure will be more stable, making it a more reliable parameter.

There are other latency measures that are also sometimes used. Maximal latency reflects the speed of conduction of the slower motor axons. Chronodispersion is measured as the difference between the shortest and longest F-wave latencies. Greater chronodispersion may indicate selective slowing of some motor axons more than others and can be expected in acquired demyelinating neuropathies (2).

Not every motor nerve stimulation results in an F wave. Persistence or penetrance is measured as the percentage of stimulations that produce an F wave. Persistence is altered by many factors (including activity level), and generally, low persistence is not considered a diagnostic finding (7). Absence of F waves, however, is considered abnormal.

Amplitude of the F wave can be measured, usually as a percentage of the corresponding CMAP. This, however, is also variable and is usually not used as a diagnostic finding.

As above, there are many measures one can obtain from F waves. A problem is that each measure has a false-positive rate which, if the reference (normal) values were analyzed optimally, is about 2.5%. As one performs more comparisons with reference (normal) data, each comparison roughly adds 2.5% to the false-positive rate. Thus, if one were to analyze minimal latency, mean latency, chronodispersion, persistence, and amplitude, there is roughly a 12.5% chance that at least one of these five measures would be “abnormal” in the healthy population. Consequently, it is this author’s preference to only measure the mean or minimal latency or indicate if the response is absent.

Although F waves will be abnormal in many clinical settings, they provide unique information in relatively few diagnoses. Probably the most useful setting for F waves is when evaluating for acquired demyelinating polyneuropathies, such as acute inflammatory demyelinating polyradiculoneuropathy (AIDP or Guillain-Barre syndrome) (8). In these disorders, the most proximal and distal ends of the peripheral nervous system (i.e., roots and distal axons) are affected first. As a result, one of the earliest findings on nerve conduction studies is absence of F waves or prolongation of F-wave latencies, presumably reflecting slowing or conduction block at the root level. This may be the only finding in some cases.

F waves also provide unique information regarding proximal conduction in early traumatic nerve lesions and will demonstrate changes before distal axon wallerian degeneration occurs and before changes appear on needle EMG. There is some evidence that F waves may change after walking in lumbar spinal stenosis (9), though it is unclear how F waves should contribute to the diagnosis of lumbar spinal stenosis (10).

There are a number of limitations to be aware of when employing F waves for diagnostic evaluation. First, since they involve only a few of the total pool of motor axons, lesions affecting only some of the axons can be missed. For instance, F waves are generally not helpful for detecting radiculopathies (11), although some authors have reported frequent abnormalities (12). Since most muscles have more than one root supplying them, normal F waves can be obtained via the other root supply,

thereby bypassing slowing via the involved root. Another limitation is that F waves measure conduction over a long distance. This limits their ability to detect focal pathology that causes only focal slowing across a short segment of nerve, which is then diluted by much longer segments of normal nerve conduction. In addition to the above, F waves are generally applicable to only distal limb muscles. In proximal muscles, the F-wave latency is so short (it does not have far to go to the spinal cord and back) that the F wave is buried in the CMAP response.

H waves (named after Dr. Hoffman) utilize a pathway similar to a muscle stretch reflex (2). In a muscle stretch reflex, the receptors in the muscle spindle are activated by sudden stretch of the muscle. This sends a wave of depolarization proximally up the large-diameter Ia sensory fibers to the spinal cord. At the spinal cord, there is a monosynaptic reflex to the  $\alpha$ -motor neuron, and the descending motor axons are activated. H waves use a similar pathway, but the wave of depolarization starts at the Ia afferent fiber instead of the muscle spindle (13).

In normal healthy adults, H waves are easily elicited primarily in the soleus and the flexor carpi radialis muscles. Young children have H waves in many more muscles (before descending inhibitory motor pathways are fully developed). Patients with upper motor neuron lesions will also have easily elicited H waves in many other muscles (14).

When recording H waves, the sweep speed needs to be slow enough to capture the response (50 ms analysis times in the upper limb and 100 ms in the lower limb).

**FIGURE 4-6.** Tibial H wave recorded as stimulus intensity is increased (as trace number increases). Trace 7 at the top of the screen has been moved to the top for measurement. Note that as stimulus is increased, an H wave appears. With further increase in intensity, the H wave becomes smaller and the M wave (CMAP) grows larger.

Sensitivity needs to be sufficient to observe these responses although H waves are typically larger than F waves. Similar to F waves, conventional teaching is that the cathode should be placed proximally along the nerve with the anode distally. However, one often uses less current if one stimulates through the knee, with a small 1-cm disc electrode over the tibial nerve (midway between the hamstring tendons at the popliteal fossa) and a 3-cm electrode (the type usually used as a ground electrode) anteriorly over the patella (15). Stimulation is best accomplished with long duration pulses (0.5 to 1.0 ms), since these preferentially activate the large Ia afferent nerve fibers that initiate the reflex arc (16). Stimulation should be at a level that produces the largest H wave, which is usually submaximal for the M wave (Fig. 4-6). Higher levels of stimulation are thought to inhibit H waves at the spinal level (2).

Latency is measured to the onset of the response—that is, the first departure from the baseline. Since the perceived onset will depend upon the display sensitivity (17), it is usually preferable to use a consistent display gain for measurement—ideally, the same used for one's reference values (e.g., 500  $\mu$ V per division). Latencies will depend upon height or leg length and most reference values take this into account. Side-to-side latency differences are more sensitive to detecting abnormalities than comparing a measured latency to reference values. A side-to-side latency difference exceeding 1.2 ms is likely abnormal for the tibial H wave (18). Amplitude of the H wave is variable and is also best compared to the other side. When the smaller response is less than 40% of the larger response, this is likely abnormal (18).

Although H waves will be abnormal in many clinical settings, they provide unique information in relatively few diagnoses. Probably the most useful setting for H waves is when evaluating for S1 radiculopathies. H waves are likely more sensitive for detecting S1 radiculopathies than is needle EMG (19). It is postulated that H waves can detect demyelination or sensory axon loss, while needle EMG only detects motor axon loss. H waves, however, provide less information about acuity or chronicity than needle EMG; they usually disappear early (or immediately) after onset of a radiculopathy and often never return. Obtaining and measuring H waves in the upper limbs are more challenging. They are somewhat more difficult to elicit than in the lower limb, and the onset is often obscured by the preceding M wave.

The A wave is another response that is sometimes noted during studies in which one is trying to record late responses. The A wave is a stable, small response that is the same with every stimulation (Fig. 4-7). A waves can appear with either submaximal or supramaximal stimulation. The proposed physiology is activation of motor axons due to either axon branching (usually seen with submaximal stimulation) or ephaptic transmission (seen with supramaximal stimulation) (Fig. 4-8). These are usually considered abnormal, though they are sometimes seen in the tibial nerve of healthy individuals (20). When seen with only submaximal stimulation, they may represent chronic nerve lesions with subsequent reinnervation

FIGURE 4-7. A wave.

and axon branching (21). A waves elicited with supramaximal stimulation are likely due to ephaptic transmission. These are sometimes seen in acute demyelinating polyneuropathies (e.g., AIDP) since demyelination creates an ideal setting for ephaptic transmission (see Fig. 4-8).

### Needle EMG

Needle EMG is a very sensitive and useful technique for detecting pathology in the lower motor neuron, NMJ, and muscle. Key to an understanding of needle EMG is a familiarity with the concept of the motor unit (Fig. 4-9). The motor unit consists of the motor neuron cell body (which, for the limbs, resides in the anterior horns of the spinal cord), the axon, and all the muscle fibers the axon supplies. The number of muscle fibers innervated per axon varies widely. For small muscles that control very fine movements (e.g., extraocular muscles or laryngeal muscles), there may be only 4 to 6 muscle fibers per axon. In large muscles for which force is more important than fine control, such as the quadriceps, there are 500 or more muscle fibers per axon.

**FIGURE 4-8.** Potential A-wave mechanisms. On the **left**, branched fibers can produce a consistent late response if one branch is stimulated, but the other is not (i.e., submaximal stimulation). On the **right**, demyelination can produce A waves by ephaptic transmission. When stimulation occurs distally, the faster fiber has already depolarized in the site of demyelination by the time the slower fiber reaches the area and direct activation of the faster fiber can occur.

In healthy individuals, if one puts a recording needle into a limb at rest, it is usually electrically quiet. When the individual gives a small voluntary contraction and activates the motor unit, a motor unit action potential (MUAP) can be recorded from the muscle (see Fig. 4-9). The MUAP represents the synchronous discharge of all the muscle fibers supplied by the axon. As more force is produced, these MUAPs fire more rapidly, and additional motor units are recruited until there are many MUAPs firing rapidly and none can be individually distinguished.

There are a number of potentials that can be recorded at rest (spontaneous potentials), some in healthy individuals, but most representing disease processes. When moving the needle electrode through the muscle, there is normally a brief electrical discharge from the muscle, known as insertional activity. This is usually high frequency and brief, usually lasting less than 300 ms (depending to some extent on the examiner).

**FIGURE 4-9.** The motor unit. Each axon supplies from a few to hundreds of muscle fibers. The MUAP is recorded from muscle fibers of the motor unit that are within the recording volume of the electrode.

Insertional activity can be prolonged, with discharges persisting longer after needle movement than normal. Prolonged or increased insertional activity can be seen in early denervation, in some myopathies, and in some inherited syndromes (22) but is usually not considered diagnostic when seen in isolation. Reduced insertional activity is measured along a different dimension than increased insertional activity (which is measured in time). Reduced insertional activity refers to reduced amplitude or absence of the burst of muscle fiber discharges when moving the needle through muscle. Reduced insertional activity is seen when there are no resting muscle membrane potentials in the area of study, such as muscle fibrosis (long-term denervation), muscle necrosis (e.g., compartment syndrome) (23), or if it is not in muscle (but, for instance, in adipose tissue).

In healthy individuals, one can easily enter the motor point of the muscle where there are abundant NMJs. When this occurs, one records endplate noise and endplate spikes. Endplate noise consists of small irregular potentials that sound (when played over a loudspeaker) like the sound of a seashell held up to one's ear. They result from spontaneously released vesicles of acetylcholine (miniature endplate potentials or MEPPs). Endplate spikes are very brief (<5 ms duration) spikes with initially negative (upward) deflections, and they create a sputtering irregular sound similar to fat in a frying pan. They result from MEPPs summing to form localized endplate potentials (EPPs). These are normal findings, but one should pull back the needle electrode slightly and move to a different area for two reasons. These are typically painful areas to explore, and the endplate spikes, when viewed from a distance, can take on an initial positivity and look like fibrillation potentials.

Fibrillation potentials and positive sharp waves represent abnormal spontaneous single muscle fiber discharges and are frequently seen in lesions of the lower motor neuron or muscle

**FIGURE 4-10.** After axon loss, fibrillations and positive sharp waves are recorded. These represent abnormal, spontaneous single muscle fiber discharges.

(24). They both represent single muscle fiber discharges and are seen in mostly the same disorders. Fibrillation potentials (Fig. 4-10) are short duration (1 to 5 ms), regularly firing spikes with an initial positivity (downward deflection). They are likely recorded by the needle electrode from outside the muscle fiber. Positive sharp waves (see Fig. 4-10) have a sharp initially positive (downward) deflection but have a duration of 10 to 30 ms, and they fire regularly. It is suspected that positive sharp waves are recorded from pierced or injured muscle fibers.

Both fibrillation potentials and positive sharp waves are seen in a variety of disorders and neither is specific to denervation (hence one should not use the term denervation potentials). They are commonly seen in disorders of motor neurons, motor axons, the NMJ (presynaptic more commonly than postsynaptic), and muscle (inflammatory myopathies and dystrophies more commonly). Upper motor neuron lesions (e.g., spinal cord injury, stroke, and traumatic brain injury) can also produce fibrillation potentials and positive sharp waves in weak muscles, though less commonly than lower motor neuron lesions do.

When fibrillation potentials and positive sharp waves are recorded, one usually grades them on a 1+ to 4+ scale (see table). The examiner should remember that this is an ordinal scale but not a ratio or interval scale. Thus, we know that a grading of 2+ represents more axon loss than 1+, but not necessarily twice as much. Moreover, a finding of 4+ fibrillations does not mean that all axons have been lost—this can be seen in very partial axon loss (25). Some authors have reported that positive sharp waves and fibrillations can be seen in normal paraspinal and foot muscles (26–28), but other authors have not found this to be common (29).

### Fibrillation and Positive Sharp Wave Grading

Grade	Characteristics
0	None
1+	Persistent single runs >1 s in two areas
2+	Moderate runs >1 s in three or more areas
3+	Many discharges in most muscle regions
4+	Continuous discharges in all areas of the muscle, baseline often obscured

Complex repetitive discharges (CRDs) can be seen in a variety of chronic neuropathic and myopathic conditions. It is believed that CRDs result from abnormal muscle membranes that allow ephaptic transmission (i.e., a depolarizing muscle fiber activates an adjacent muscle fiber via local currents, not via any synapse). A pacer muscle cell fires regularly, thereby activating adjacent muscle fibers, which then fire in a sustained rhythmic pattern. CRDs are constant iterative discharges that appear and disappear suddenly without much variation in firing rate or amplitude. They sound like steadily operating machinery. They are not usually considered normal findings but suggest chronic axon or muscle fiber loss. CRDs are most commonly seen in chronic neuropathic and myopathic conditions but are not specific to either one. Some authors report that they can be found normally in select muscles such as the iliopsoas (30). If they are found in a myotomal distribution, they can be considered diagnostic of radiculopathy (11).

Fasciculation potentials represent spontaneous discharges of an entire motor unit or a large part of a motor unit. They often originate in the anterior horn cell but can also originate distally along the axon or a branch of the axon (31). Fasciculation potentials are recognized by their appearance and rhythm of firing. Individually, they look just like a single motor unit. However, they can be distinguished from a voluntary motor unit by their random discharge rate. These discharges are also spontaneous and not under voluntary control. To observe fasciculation potentials, one must often wait with the needle quietly in the muscles without moving the needle for a minute or more. Altering the sweep speed to a slower sweep (e.g., 100 ms per division) is often helpful. Fasciculations otherwise could be easily missed when one is rapidly looking through a muscle on a faster sweep speed.

Fasciculation potentials can be seen in a variety of disorders. Most commonly, one sees benign fasciculations. When asked, approximately 50% of people report fasciculations in their calves, worse with activity and sometimes increased with the use of caffeine (32). Fasciculation potentials are also seen in thyrotoxicosis and exposure to anticholinesterase medications. They can be seen in radiculopathies and chronic neuropathies as well. Perhaps the most worrisome disease in which fasciculations can be seen is motor neuron disease. Amyotrophic lateral sclerosis (ALS), progressive bulbar palsy (PBP), and other variants of motor neuron disease can all present with fasciculation potentials. The primary way

in which benign fasciculations can be distinguished from those associated with disease is by the “company they keep.” In motor neuron and other progressive disease processes, one will often see fibrillation potentials, positive sharp waves, and large amplitude long duration motor unit potentials, along with the fasciculation potentials. Benign fasciculations do not present with these other findings. When comparing fasciculations associated with motor neuron disease to those in benign fasciculations, there are some other minor differences, but these are not sufficient to be diagnostic by themselves. Fasciculations associated with motor neuron disease tend to be less frequent in firing rate, and they tend to be larger in amplitude, polyphasic, and longer duration (reflecting the concurrent ongoing reinnervation).

Myokymia is often thought of as a grouped fasciculation. Myokymic discharges represent groups of motor units firing in a burst pattern (usually with a regular burst rate) (33). These discharges, when played over the EMG instrument’s loudspeaker, are often described as sounding like marching soldiers. However, the bursts can be quite different in both their duration and discharge rate making recognition sometimes difficult. Myokymia is distinguished from CRDs because of the bursting nature rather than a single on and off with constant firing as seen in CRDs. Myokymic discharges are also distinguished from myotonic discharges because the former do not change in firing frequency or amplitude. Myokymia can be seen in a variety of conditions and is usually thought of separately for facial myokymia and limb myokymia. In facial myokymia, one often thinks of multiple sclerosis, pontine gliomas, and other brainstem disorders. In the limb, myokymia can be seen in some chronic compressions such as radiculopathies and entrapment neuropathies.

It is probably most important to remember that limb myokymia can occur in the presence of radiation plexopathy (34). This is useful when patients have had radiation for breast cancer, Hodgkin’s lymphoma, or other malignant tumors. Occasionally, these patients will present with a later-onset plexopathy, and the diagnostic question is whether the plexopathy represents tumor invasion or delayed-onset radiation plexopathy. Tumor invasion in the brachial plexus tends to present with pain, lower trunk lesions, and a Horner’s syndrome. Radiation plexitis presents with upper trunk lesions, paresthesias, and myokymia. Thus, myokymia argues for a diagnosis of radiation plexopathy in these cases.

Myotonia is a discharge that originates in single muscle fibers. It is believed to be due to abnormal chloride conductance across the muscle cell membrane. These discharges are noted by their unique waxing and waning quality, both in frequency and in amplitude. Because the firing frequency changes, the pitch produced over the loudspeakers changes as well, and one hears sounds often described as a “dive bomber” or “revving motorcycle.” The amplitude of the response also changes over time making the sound louder and softer during the discharge pattern. This can be distinguished from CRD because of its changing nature (CRDs are noticeably constant in firing frequency and amplitude).

Myotonia can be seen in a variety of muscle diseases including myotonic dystrophy, myotonia congenita, paramyotonia, and other disorders (35). Myotonic dystrophy is an unusual myopathy in that distal muscles are affected more than proximal muscles, and the same is true for where one might record these discharges. Distal hand muscles (e.g., first dorsal interosseous [FDI]) are often most affected. Myotonia is often worsened by cold and can be brought out by icing the distal part of the limb before recording. Myotonic discharges are also reduced immediately after exercise. Since myotonia originates from muscle, it is not expected in patients with neuropathic disease.

A possible variant of myotonia is the syndrome of diffusely abnormal increased insertional activity, also known as “EMG disease.” This disorder is an autosomally dominant inherited syndrome and presents with increased insertional activity and persistent positive sharp waves in essentially all muscles tested in the body (22). One can tell, however, that the patient does not have a true neuropathic disease because there are no fibrillation potentials, motor unit potentials are normal in morphology and size, and recruitment is normal. Because of the diffuse positive sharp waves, these patients can often be erroneously diagnosed with motor neuron disease or other serious disorders. It is difficult to know whether this syndrome produces symptoms or not, since those coming to the EMG laboratory are usually selected for some symptoms to start with. However, relatives of the patient with this disorder are often asymptomatic.

### Motor Unit Analysis

Analysis of MUAPs yields important information about the integrity of the motor unit and whether there are changes in axons, muscle fibers, or the NMJ. The MUAP, as mentioned earlier, represents the synchronous discharge of all the muscle fibers supplied by a single motor neuron. Duration of the MUAP is largely influenced by the size of the motor unit territory, that is, the number of muscle fibers supplied by the single axon that are within the recording area of the needle electrode. Duration of the MUAP is not markedly affected by proximity of the depolarizing muscle fibers to the needle electrode.

Amplitude of the MUAP is also related to motor unit territory but is more influenced by the proximity of the discharging muscle fibers to the recording electrode. When the needle is close to the depolarizing muscle fibers, the amplitude is much larger than when it is some distance away. Thus, motor unit duration is a more reliable indicator of motor unit territory than is amplitude. There are reference values established for concentric electrodes for most of the major muscles in the body (36). These vary according to muscle and age. More proximal muscles, and especially bulbar muscles, have shorter duration MUAPs. MUAP duration tends to increase with age. There are not well-established reference values for monopolar electrodes. Thus, when performing quantitative MUAP analysis, one should use a concentric electrode.

Polyphasicity is noted when there are more than five phases of an MUAP. A phase represents a change in direction that crosses the baseline. Thus, one can calculate the number of

**FIGURE 4-11.** After partial axon loss and reinnervation by axonal sprouting, intact axons send new sprouts out to denervated muscle fibers. When the intact axon then fires, it is larger, polyphasic, and longer in duration.

phases as the number of baseline crossings plus one. Changes in the direction that do not extend across the baseline are not counted as a phase. The presence of polyphasicity alone is usually not diagnostic, since most normal muscles have a small percentage (approximately 20%) of polyphasic MUAPs. However, polyphasic, long duration, large amplitude MUAPs are usually seen in neuropathies, and polyphasic, short duration, small amplitude MUAPs are typically seen in myopathic conditions.

In neuropathic conditions, two types of reinnervation may be noted that change the MUAP morphology. When incomplete nerve injuries are present, some axons are spared, and others undergo wallerian degeneration. In this case, the remaining axons send distal sprouts to reinnervate the denervated muscle fibers. These sprouts are initially poorly myelinated and immature, which results in less synchronous discharge of muscle fibers than seen normally. When this distal axonal sprouting happens, one will observe polyphasic long-duration large-amplitude MUAPs (Fig. 4-11). As the new sprouts mature, the polyphasicity is reduced because the new sprouts become better myelinated and the muscle fibers fire synchronously again. Thus, late after reinnervation by axon sprouting, the examiner will see large amplitude long duration but not polyphasic MUAPs.

In cases of complete nerve transactions or complete axon loss, the picture is different. In these cases, there is no distal axonal sprouting because there are no viable distal axons. Rather, one is dependent upon axons regrowing from the site of injury down to the muscle. When these new axons first reach the denervated muscle, they innervate just a few muscle fibers. These new MUAPs (which used to be called nascent potentials) are typically short in duration, polyphasic, and small in amplitude because the axons have supplied only a few muscle fibers. As these axons continue to sprout, they become

larger and longer duration and retain polyphasicity until the new sprouts mature several months after reinnervation.

Whether reinnervation occurs by distal axon sprouting or axon regrowth from the site of injury, recruitment will be reduced or discrete. Because there are fewer MUAPs, the existing motor units will fire more rapidly than normal, and there will be fewer MUAPs firing even with maximum contraction.

The model for myopathic changes in MUAPs can be thought of as random loss of muscle fibers within the motor unit (Fig. 4-12). In this case, since there are reduced numbers of muscle fibers, the MUAP duration and amplitude will be reduced. These MUAPs are polyphasic possibly due to less muscle fibers in the motor unit or possibly due to temporal dispersion along muscle fibers that conduct at different speeds in the setting of disease. In either case, in myopathies, one sees small-amplitude short-duration polyphasic MUAPs. These MUAPs are recruited early with many MUAPs appearing on the EMG screen with even small amounts of force generation. It is difficult to isolate a single MUAP in patients with the most severe myopathies.

NMJ disease can look, in many ways, just like a myopathy on needle EMG. Since the NMJs in a muscle do not all fire in these cases, there are less functional muscle fibers per motor unit, and the duration and amplitude of the MUAPs will be reduced. A feature commonly found in NMJ disease that is not seen in myopathy, however, is that of motor unit instability. Since the NMJs will fire variably and unreliably, the entire MUAP will vary in its size and morphology as muscle fibers fire or do not fire with each successive MUAP discharge. This motor unit instability can be seen in NMJ disease as well as in recent reinnervation, since in the latter case the NMJs are also not mature and reliable. To observe motor unit instability, it is most helpful to look at MUAPs with a trigger and delay line

**FIGURE 4-12.** Myopathic MUAPs can be thought of as resulting from partial muscle fiber loss. With few muscle fibers in the MUAP, duration is shorter, amplitude is reduced, and there are more polyphasic MUAPs. The patient recruits more MUAPs for small levels of force since each MUAP creates less force than normal (early recruitment).

so that the MUAP fires repetitively at the same location on the screen.

While one typically evaluates MUAPs in a semiquantitative fashion, there are situations in which it is important to evaluate MUAPs more quantitatively. In the setting of possible myopathy, it is often very important to quantitatively measure MUAP duration to see whether it is shorter than reference values. Myopathies are sometimes more difficult to diagnose without quantitative analysis than neuropathic conditions, since one more frequently lacks the abnormal spontaneous activity or abnormal nerve conduction that are present in a neuropathic lesion.

To perform quantitative needle EMG, one must change the technical aspects of data collection in several ways. First, most reference values have been collected using concentric needle electrodes rather than monopolar needle electrodes. The concentric electrode has the advantage of a smaller recording volume and better reliability in duration measurements. Thus, one must use a concentric electrode. Normally, filters for needle EMG are set roughly from 20 Hz to 10 kHz. The low-frequency filter setting of 20 Hz is sufficient for capturing most electrophysiologic muscle potentials and reduces baseline wander, but it also distorts the low-frequency initial and terminal phases of the MUAP where departure from and return to baseline are gradual. For these reasons quantitative needle EMG requires that the low-frequency filter be reduced to 2 Hz, and multiple firings of individual MUAPs are averaged to present a clean single MUAP.

Multiple studies have been reported dating from the 1950s looking at how many MUAPs need be collected to obtain a reproducible mean MUAP duration for a particular muscle. These studies have shown that minimally 20 different MUAPs should be collected to obtain a reproducible value for mean MUAP duration, unless there are extremely abnormal MUAPs (37). Twenty different areas of the muscle should be studied, and this can usually be accomplished with only three to five different needle insertions through the skin. While quantitative needle EMG is commonly used in the setting of myopathy, generally only one or two muscles are studied this way. It is less common to use quantitative needle EMG in multiple muscles or in many neuropathic conditions where there are other hints of neuropathies.

After MUAPs are assessed, the electrodiagnostic medical consultant should then evaluate MUAP recruitment. Normally, when one provides a very small force, one will recruit a single motor unit firing slowly, typically about 5 Hz. As more force is exerted, this MUAP will speed up to 10 to 12 Hz and produce greater levels of force. However, as the firing rate reaches about 12 to 15 Hz (depending on the muscle), a second MUAP is then recruited to allow additional force production. In this way, muscle forces are generated both by increasing rates of MUAP firing and by increasing the number of MUAPs firing. Normally, at full contraction, there are many MUAPs firing rapidly and the baseline cannot be distinguished. There are generally three types of abnormalities of recruitment. Sometimes, patients have insufficient central drive from the upper motor neurons to generate high levels of MUAP firing. This could be due to pain, poor voluntary effort, or upper

motor neuron lesions. In these cases, one sees less than the full number of MUAPs, but the ones that are present fire slowly due to reduced upper motor neuron drive. This is often termed central recruitment.

In other cases, there is sufficient upper motor neuron drive, but there are reduced numbers of motor units available to participate in force production. In these cases, the initial MUAPs fire more rapidly before a second MUAP is recruited because there are fewer motor units available to recruit. In extreme cases, there may only be one or two MUAPs firing very rapidly (up to 30 to 40 Hz) without any additional MUAPs present. This is typically termed reduced recruitment (or in cases where there are only very few MUAPs, discrete recruitment). It is distinguished from central recruitment in that the MUAP firing rate is quite fast.

A third abnormality one can see in MUAP recruitment is early recruitment. This is typically seen in myopathies or NMJ defects. With early recruitment, since each MUAP in a myopathy produces less force than normal, more motor units are recruited sooner or earlier than normal for a given level of force generation. The examiner asks the patient to produce a small amount of force and sees many MUAPs firing, more than expected for that level of force. In many cases of early recruitment, it is difficult to have a patient fire just one MUAP; it is usually either many or none. Thus, early recruitment represents many MUAPs firing for a low level of force production. Assessing early recruitment requires both measurement of force (whether qualitative or quantitative) and observation of MUAP firing patterns.

## Repetitive Stimulation Studies

Repetitive stimulation studies are primarily useful for detection of NMJ abnormalities. To understand the underlying reasoning of how one performs NMJ studies, one needs to first review the physiology of NMJ, which is well described elsewhere (38).

Normally, when a motor axon is depolarized, the wave of polarization travels toward the axon terminal as a result of the propagation of opening and closing of sodium channels. When it reaches the terminal end of the motor axon near the end plate, voltage-gated calcium channels are activated. The opening of these channels allows an influx of calcium ions ( $\text{Ca}^{2+}$ ) into the presynaptic terminal. The opening of the voltage-gated and dependent calcium channels and the resulting calcium ion influx result in an increase of intracellular  $\text{Ca}^{2+}$  at the presynaptic terminal for about 100 to 200 ms before the  $\text{Ca}^{2+}$  is pumped out and the intra-axonal  $\text{Ca}^{2+}$  is returned to the resting concentration. This influx of calcium, however, allows the acetylcholine vesicles to fuse with the presynaptic membrane and release their quanta of acetylcholine into the extracellular space at the synapse.

At rest, the presynaptic terminal has occasional spontaneous release of quanta of acetylcholine that occur irregularly (38). When these quanta reach the postsynaptic terminal, they create MEPPs. However, when the presynaptic axon is excited or depolarized, the release of quanta is much greater. A high

**FIGURE 4-13.** The amount of acetylcholine released with successive stimulations at 3 Hz drops. However, in the presence of a normal threshold for muscle fiber activation (normal safety factor), this drop is not noted. When the threshold is elevated and the safety factor reduced, some muscle fibers may not be activated.

concentration of acetylcholine is generated, which in turn activates the muscle fiber. In healthy individuals, the presynaptic terminal releases three to five times as much acetylcholine as is required to activate the postsynaptic membrane of the muscle fiber. This extra amount of acetylcholine release is known as the safety factor. While there is normally a large safety factor for the first discharge of a motorneuron, the amount of acetylcholine released drops with successive discharges when the nerve is activated at 2 to 3 Hz. However, because the safety factor is so large, there is still more than enough acetylcholine to activate the muscle fiber (Fig. 4-13).

Once the acetylcholine is released into the synaptic cleft, it encounters acetylcholinesterase, the enzyme so named because it hydrolyzes acetylcholine molecules. This enzyme does not “know” whether the acetylcholine it is digesting has recently come from the presynaptic terminal or has already been used to activate the postsynaptic receptors. It digests the acetylcholine it encounters either way. Due to this enzymatic activity, it is estimated that only about half of the acetylcholine released from the presynaptic terminal makes it to the postsynaptic receptors. Once the acetylcholine reaches the postsynaptic receptors, it creates localized areas of membrane depolarization known as EPPs. These EPPs then summate to create a muscle membrane depolarization, and the muscle fiber discharges.

Exercise also has significant influences on NMJ physiology. Immediately after exercise, one sees postexercise potentiation or facilitation. In part, this is due to the fact that motor units fire at rates approaching 30 Hz with full voluntary contraction. At these rates, there is only roughly 33 ms between each axon depolarization, which is less than the time needed for the  $\text{Ca}^{2+}$  to be pumped out of the presynaptic terminal. Thus, with exercise,  $\text{Ca}^{2+}$  builds up in the presynaptic terminal, and this further facilitates release of acetylcholine. When the safety factor is intact, this is not noticed because there is already more than enough acetylcholine to fully depolarize the muscle fiber. However, when the safety factor is reduced in disease states, some NMJs do not fire, and postexercise potentiation will create a larger amplitude CMAP than preexercise. This is termed postexercise facilitation.

There is also a phenomenon of postexercise exhaustion, which occurs 2 to 4 minutes after sustained exercise. In this period of postexercise exhaustion, there is less acetylcholine released than in the preexercise condition. Again, in healthy individuals, this would not be noticed because of the large safety factor. However, in individuals with marginal or reduced safety factors, some NMJs will not fire, and the CMAP will be reduced in amplitude.

There are several elements of the electrodiagnostic examination to keep in mind when evaluating an individual with possible NMJ disease (39). First, one should perform a standard motor nerve conduction study of the muscle and nerve to be studied with repetitive stimulation. This is to both assess the resting amplitude of the response as well as be sure that the nerve under study does not have a prior or subclinical injury that could alter the results of NMJ testing.

The second step is to record the distal CMAP at rest and then again *immediately* after 10 seconds of maximum voluntary isometric exercise (Table 4-1). This procedure is used to look for any postexercise facilitation. When presynaptic diseases of the NMJ are present, the initial resting CMAP will be low in amplitude but will increase markedly after 10 seconds of exercise, since  $\text{Ca}^{2+}$  buildup within the presynaptic terminal occurs and acetylcholine release is greatly facilitated.

The third step is to perform repetitive stimulation at slow rates of 2 or 3 Hz. Generally, trains of five stimulations are sufficient, although some laboratories use ten to look for consistency of the response. When stimulating at 3 Hz, there are 333 ms between each stimulation. This means that between each stimulation there is essentially a full return of baseline or resting state of  $\text{Ca}^{2+}$  concentration. Thus, there is no significant facilitation of acetylcholine release. As discussed above, there is depletion of the immediately available stores of acetylcholine vesicles and resultant diminution of acetylcholine release with each successive stimulation. In healthy individuals, while the acetylcholine release is reduced with each successive stimulation, the CMAP remains stable and unchanged because of the large safety factor. Most laboratories consider amplitude decrements of less than 10% between the first stimulation and the

**TABLE 4.1 Findings at Different Stimulation Frequencies and in Different Diseases**

	Healthy	Myasthenia Gravis	LEMS
Single CMAP at rest	Normal	Normal	Small
Compare single CMAP immediately after 10-s exercise	No $\Delta$	No $\Delta$	$\uparrow\uparrow$ >100% increase
<i>Preexercise</i>	No $\Delta$	Decrement >10%	Decrement >10% but all responses are very small
3-Hz stimulation compare first to fifth	No $\Delta$	Less decrement than preexercise	Decrement >10% but all responses are bigger than preexercise
<i>Postexercise potentiation</i>	No $\Delta$		
3-Hz stimulation compare first to fifth immediately after 30 s exercise	No $\Delta$		
<i>Postexercise exhaustion</i>	No $\Delta$	Decrement >10%, more pronounced than preexercise	Decrement >10% with all responses small as preexercise
3 Hz stimulation compare first to fifth 2–4 min after 30 s exercise	No $\Delta$		
<i>High-frequency stimulation</i>	$\uparrow$	$\uparrow$	$\uparrow\uparrow$
30–50 Hz stimulation comparing last to first	$\leq 40\%$ increase	$\leq 40\%$ increase	>100% increase

fourth or fifth to be normal. However, in the setting of NMJ diseases, when the safety factor is diminished, a reduction in CMAP with progressive stimulations will exceed the normal range. To be considered abnormal, the reduction should be more than 10% decrement compared to the baseline value.

One must be mindful of several technical points when performing repetitive stimulation to avoid erroneous observation. First, temperature is critical. When the temperature is below 34°C, enzymatic activity of acetylcholine esterase is reduced. As a result, cold causes an increase in acetylcholine levels within the NMJ, which compensates for any pathological reduction of the safety factor. This reduces the likelihood of detecting decrements that might be present otherwise. Second, a stable recording baseline is important. The movement of the limb has to be minimized so it does not create signal artifacts in the recordings. Many laboratories will attempt to immobilize the part of the limb being studied, although this is more difficult with proximal or bulbar muscles. The choice of the nerve muscle pair is also crucial. NMJ diseases, especially myasthenia gravis (MG), tend to affect proximal muscles more than distal muscles. However, the proximal studies are technically more difficult than the more distal limb nerve muscle pairs. Thus, many laboratories will start with the ulnar nerve recording from the abductor digiti minimi (ADM). If this is normal, then most laboratories will proceed to a proximal limb muscle such as the trapezius (stimulate spinal accessory nerve) or the deltoid (stimulate at Erb's point). Finally, if these two studies are normal, then the study of the facial nerve recording from nasalis can yield important information. While the latter technique is more sensitive, it is also more vulnerable to movement artifact.

After the initial series of five stimulations at 3 Hz, one should then repeat studies both immediately after exercise (to look for postexercise potentiation) and several minutes after exercise (to look for postexercise exhaustion). After the pre-exercise testing, one asks the patient to maximally contract the muscle for 30 or 60 seconds. Immediately postexercise,

one then gives another series of five stimulations as before the exercise. This series is repeated again at 1-minute intervals until 4 minutes postexercise. By performing this procedure one assesses for postexercise facilitation (or potentiation) immediately after exercise and for postexercise exhaustion, which typically occurs at 2 to 4 minutes postexercise.

In some cases, high-frequency repetitive stimulation is used. This is particularly helpful when the patient is not able to voluntarily exercise, and when one is looking for a presynaptic disease such as Lambert-Eaton myasthenic syndrome (LEMS) or botulism. Stimulation rates are set in the 30- to 50-Hz range which means there is only 20 to 33 ms between each successive stimulation. At these rates, the subsequent stimuli occur too frequently for the presynaptic nerve terminal to pump out the extra influx of  $\text{Ca}^{2+}$ . Thus, calcium concentration builds up in the presynaptic terminal, and consequently, acetylcholine release is markedly increased. High-frequency repetitive stimulation is primarily used to look for postexercise facilitation and is mostly useful in presynaptic defects. Healthy patients have a moderate increase in CMAP size with these rates of stimulation, known as pseudofacilitation. The phenomenon is not likely due to mechanical artifact. While some have postulated that hypersynchronization of the muscle fiber action potentials is the cause, a more convincing explanation, for which there is now experimental evidence, is that the muscle fibers undergo hyperpolarization, due to the intramuscular release of norepinephrine and consequent stimulation of the electrogenic  $\text{Na}^+/\text{K}^+$  pump (40).

One generally groups NMJ defects into presynaptic and postsynaptic types. MG is the most common postsynaptic NMJ disease. The pathophysiology has been postulated to result from acetylcholine receptor antibodies likely generated from an autoimmune process. These antibodies act as antagonists against the acetylcholine receptors at the postsynaptic cleft of the NMJ. In addition, there are marked distortions of the NMJ with a widened cleft and fewer infoldings postsynaptically well

visualized on morphological studies by electronmicroscopy (41,42). This is important for electromyographers to keep in mind since the widened cleft means that there is a greater chance that acetylcholinesterase will digest the acetylcholine before it reaches the postsynaptic cleft. Moreover, for the acetylcholine molecules that do reach the postsynaptic membrane, there are fewer available receptors to activate, hence there is a much reduced safety factor.

In MG, one usually sees relatively normal CMAPs at rest and little change immediately after exercise. However, with slow repetitive stimulation (2 to 3 Hz), one will often observe a reduction in the CMAP maximal at the fourth or fifth stimulation in the series. As mentioned above, the decrement needs to be greater than 10% to be considered normal. Repetitive stimulation in these patients should also display a repair of the decrement immediately after exercise due to postexercise potentiation. At 2 to 4 minutes after exercise, when postexercise exhaustion occurs, a more marked decrement is seen than in the preexercise phase. At times, patients with more subtle disease will demonstrate no decrement preexercise but will demonstrate a significant decrement 2 to 4 minutes postexercise. Thus, when evaluating for potential MG, one should always complete the series of postexercise runs of repetitive stimulation as described above. With high-frequency repetitive stimulation, patients with MG show only small increments as do normal individuals due to pseudofacilitation (described above).

LEMS is due to an abnormality in the voltage-gated calcium channels located in the presynaptic terminal (43). It is most commonly associated with small-cell lung cancer but can also be seen in other cancers, some autoimmune disorders, and it is rarely idiopathic.

Patients with LEMS demonstrate very small CMAPs at rest (44). However, immediately after 10 seconds of exercise, the CMAP increases in size dramatically due to the enhanced release of acetylcholine precipitated by brief periods of exercise and consequent increase in calcium ion concentration within the presynaptic terminal. The results are quite striking, and few other diseases cause CMAP amplitude to increase so impressively. To be diagnostic, the increase in CMAP amplitude needs to be at least 100%, that is, a doubling of the initial CMAP. Remember that the CMAP does not increase in size above normal values, but simply goes from a very small initial amplitude to one that is closer to normal.

With repetitive stimulation at slow rates, patients with LEMS will demonstrate a decrement between the first and fourth potential that is not unlike that seen in MG. This is related to the abnormal safety factor that is seen in LEMS as well as MG. However, what will be noted is that in the series of five stimulations immediately postexercise, all of the CMAPs will be much larger than they were in the preexercise condition. At 2 to 4 minutes postexercise, the CMAPs fall to their baseline levels, and the results become similar to what was seen at rest.

It is in the setting of LEMS that high-frequency repetitive stimulation is most useful. With stimulation rates of

30 Hz or more, there is a buildup of  $\text{Ca}^{2+}$  in the presynaptic terminal, which tends to overcome the initial defect. As a result, the CMAP becomes more than double its resting amplitude, often approaching a near-normal amplitude.

Botulism is another example of presynaptic NMJ disease. In this case, it is not the voltage-gated  $\text{Ca}^{2+}$  channels that are impaired but rather the ability of the presynaptic vesicle membrane to fuse with the axon terminal plasma membrane and release acetylcholine (45). The effect of botulism on electrodiagnostic findings is conceptually similar to that seen in LEMS. However, in the real world, the presentation of botulism tends to be more variable and not all cases will have marked increments with fast repetitive stimulation or marked postexercise facilitation.

There are a number of limitations in NMJ testing. First, the sensitivity of repetitive stimulation studies is probably only about 60% to 70% in cases of MG, even with technically well-performed studies utilizing exercise (46,47); specificity, however, is very good. The reasons for only moderate sensitivity are likely multifold and are beyond the scope of discussion here. Single fiber EMG, which is not being reviewed in this chapter, has a greater sensitivity than repetitive stimulation. Similarly, repetitive stimulation is not as sensitive for presynaptic lesions as is single fiber EMG. Another limitation is that cold can have a significant influence on these studies and cause false-negative results. Patients who are on anticholinesterase medication such as pyridostigmine will not demonstrate the same degree of abnormalities as those who are without the medication. Finally, good examiners always keep in mind the technical aspects, with the most concerning one being errors introduced by limb movement. With repetitive stimulation, there is often considerable limb movement unless one is vigilant. Limb movement alters the position of the recording and stimulating electrodes, and their contact to the skin. In this way, movement can bring the stimulation to less than supramaximal, which could mimic a decrement.

## DISEASE PROCESSES

### Entrapment Neuropathies

There are a variety of entrapment neuropathies that commonly present to the electrodiagnostic laboratory for evaluation. The most common ones, which will be discussed here, include median neuropathy at the wrist (carpal tunnel syndrome), ulnar neuropathy at the elbow, radial neuropathy at the spiral groove, fibular neuropathy at the fibular head, and tarsal tunnel syndrome.

There are a few general concepts regarding entrapment neuropathies that can be useful to keep in mind as one evaluates these various neuropathies. First, entrapment of a nerve typically first produces demyelination and consequent conduction slowing in more mild cases. As the demyelination progresses, the electrophysiologic changes progress from slowing to conduction block. With more severe entrapments, axon loss can occur. There is some variation in this general principle across nerves since some nerves, such as tibial nerve at the

ankle or ulnar nerve at the elbow, are more prone to axon loss than others such as the median nerve at the wrist or the fibula nerve at the knee.

A second generalization is that the largest diameter fibers are affected first in an entrapment neuropathy. This means that the large-diameter sensory fibers will first demonstrate slowing and conduction block, and only with more progressive lesions will the slightly smaller diameter motor fibers be affected.

A third principle is that nerves are made up of fascicles and not all fascicles are affected equally by an entrapment lesion. For example, ulnar neuropathy at the elbow often spares fascicles supplying the two ulnar innervated forearm muscles, flexor carpi ulnaris, and flexor digitorum profundus (48). Similarly, in the median nerve at the wrist, the fascicles supplying the ring finger and long finger are more commonly affected than those supplying the index finger (49). In the fibular nerve at the fibular head, it is more common to have deep fibular nerve involvement than it is to have changes in the distribution of the superficial fibular nerve. These variations in fascicular vulnerability mean that one will want to customize the electrodiagnostic examination and interpretation with this in mind. For instance, one would not assume that if there is evidence of denervation in ulnar innervated hand muscles, but forearm muscles are normal, the lesion is distal to the elbow or at the wrist.

Perhaps the most important principle to remember is that one should think about one's approach carefully before starting the evaluation. Clinicians can run into a common pitfall by doing is to do some initial testing and, if findings are normal, then completing additional testing. Since each test performed carries a 2.5% false-positive rate, more tests will introduce a higher rate of false-positive error if not analyzed appropriately.

### Median Neuropathy at the Wrist

Median neuropathy at the wrist, which is usually responsible for carpal tunnel syndrome, is the most common entrapment neuropathy to be referred to electrodiagnostic laboratories in the United States (50). Symptoms commonly include hand numbness and weakness (51). The patient often does not localize the numbness to simply the median distribution but rather indicates that the whole hand becomes numb (52). A complaint of dropping things is frequent. Symptoms are usually worse at night, and patients may occasionally report they "flick" their wrist to relieve symptoms.

On examination, one can find weakness of the thenar muscles and possibly some mildly reduced sensation. There are a number of physical signs such as Tinel's sign, Phalen's sign, and the flick sign that are suggestive of carpal tunnel syndrome. However, the sensitivity and specificity of these tests are not high (1) and they should not be used to make or rule out a diagnosis.

There are number of risk factors for carpal tunnel syndrome that have been well documented in the literature (53). In polyneuropathies, nerves are more susceptible to superimposed entrapment such as in diabetes mellitus. Diseases in which there

is more synovial tissue at the wrist such as rheumatoid arthritis also increase the risk of carpal tunnel syndrome by about threefold. Individuals who have manual work that involves high repetition and high are at significantly increased risk of carpal tunnel syndrome. Obesity is also a risk factor (54).

Since detection of slowing of median nerve conduction across the wrist is the most useful way to localize the entrapment neuropathy, this should be the focus of one's electrodiagnostic assessment. There have been many approaches described for diagnosing carpal tunnel syndrome with nerve conduction studies. For a more in-depth coverage, readers are encouraged to review other articles (55,56). One's general approach should be to measure sensory and motor conduction across the wrist and to compare the latencies with nearby nerves in the hand, such as the radial or ulnar nerve, that do not traverse the carpal tunnel. This helps to exclude the effects of temperature, age, and other factors such as polyneuropathy, which may influence nerve conduction. As is the case in most entrapment neuropathies, sensory fibers are usually affected first. Rarely, motor axons are preferentially affected, possibly because of focal compression of the recurrent branch of the median nerve or selective effects on fascicles within the median nerve at the wrist (57).

There are many approaches for evaluating median sensory conduction across the wrist, and it is critical to think through these alternative approaches before even seeing the patient. In particular, as mentioned above, one should not adopt the methodology of performing one test and, upon finding a normal result, performing another test until one finds an abnormality. Although this might seem tempting intuitively, it is risky since each additional test performed carries a 2.5% false-positive rate, which is roughly additive as each new test is performed.

When selecting sensory nerve conduction studies, one should select studies that are (in descending order of importance)

- Specific (few false positives)
- Sensitive (few false negatives)
- Reliable (obtain the same results today and tomorrow)
- Not influenced by covariates such as temperature and age

There are three sensory conduction studies that have been shown to be reasonably good in terms of the criteria mentioned above (58). These are demonstrated in Figure 4-14. Comparison of median and ulnar conduction to the ring finger allows the detection of slowing of median conduction in comparison to the ulnar nerve, which does not traverse the carpal tunnel. A median-ulnar difference exceeding 0.4 ms is likely abnormal. Similarly, comparison of the median and radial nerve to the thumb has similar advantages. Here, a difference exceeding 0.5 ms is probably abnormal. The third test is the median and ulnar comparison across the palm over an 8-cm distance. This study should demonstrate no more than a 0.3 ms difference in healthy individuals.

This author has published a method to summarize these three tests into one result known as the combined sensory index

**FIGURE 4-14.** The CSI (sometimes referred to as the Robinson index) is obtained by recording the three tests noted below. The CSI is sum of the median ulnar or median radial differences. In this case, it is  $(3.8 - 3.2) + (3.2 - 2.7) + (2.2 - 1.9) = 0.6 + 0.5 + 0.3 = 1.4$ . The upper limit of normal is 0.9 ms.

or CSI (since the television show Crime Scene Investigation has become popular, this is now being called the Robinson Index). To calculate the CSI, one performs all three of the studies mentioned above and adds the latency differences (median minus ulnar or median minus radial) together (when these are negative, i.e., the median is faster, a negative number is used). The CSI, because it summarizes three different tests, has been shown to be highly specific and more sensitive than the indi-

vidual tests (59). It is also more reliable than single tests when one studies the same patient on two different occasions (60). A CSI exceeding 0.9 ms is considered abnormal (59).

Motor nerve conduction studies are also, as mentioned above, an essential component of the electrodiagnostic evaluation of carpal tunnel syndrome. These should be performed even if sensory conduction studies are normal. Most commonly, studies are performed with stimulation of the median

nerve at the wrist and recording over the abductor pollicis brevis (APB). Generally, latencies exceeding 4.5 ms are considered abnormal. It is not particularly useful to compare one median nerve with the other side because of the frequency of bilateral CTS. However, some electromyographers compare the median motor latency with the ulnar motor latency; a difference exceeding 1.5 ms is considered abnormal. While some authors do advocate stimulating both at the wrist and at the palm (61), it is difficult to stimulate only the median nerve in the palm, and one can be easily misled into a false diagnosis if the ulnar nerve is inadvertently stimulated in the palm (62).

Needle EMG is sometimes useful in evaluating patients with carpal tunnel syndrome (63). There is not a consensus about when thenar muscle EMG should be performed. It is this author's practice to perform needle EMG of the thenar muscles in three settings:

- Patients in whom the motor response is abnormal (this group has a higher yield)
- Patients with a history of trauma (in which axon loss is more likely)
- Patients with a clinical presentation that suggests another possible diagnosis (such as radiculopathy or plexopathy)

### Ulnar Neuropathy at the Elbow

Ulnar neuropathy at the elbow is another common entrapment neuropathy presenting to the electrodiagnostic medical consultant. The etiology of ulnar neuropathy at the elbow varies but can be due to acute injury, entrapment in the cubital tunnel (under the aponeurosis between the two heads of the flexor carpi ulnaris), or prolonged stretching of the nerve in the ulnar groove when the elbow is held in the flexed position (64). Tardy ulnar palsy is a result of prior elbow injury causing an elbow deformity and slowly progressive injury to the ulnar nerve.

Symptoms of ulnar neuropathy typically include numbness over the small finger and the ulnar half of the ring finger. Generally, an ulnar neuropathy at the elbow also affects sensation over the dorsum of the hand on the ulnar side, an area supplied by the dorsal ulnar cutaneous nerve, which branches from the ulnar nerve proximal to the wrist. By contrast, ulnar nerve lesions at the wrist spare the dorsal ulnar cutaneous territory because they are distal to this branch point. Ulnar neuropathy at the elbow should spare sensation over the medial forearm. This area is supplied by the medial antebrachial cutaneous nerve originating from the medial cord of the brachial plexus and should be spared in ulnar neuropathy at the elbow.

Patients often also present with weakness of ulnar hand muscles complaining that they have difficulty holding small objects and difficulty with grip strength. They may sometimes notice atrophy of the FDI muscle. At times, they will report that when they put their hand into their pocket, the small finger does not make it in. This is known as Wartenburg's sign and reflects weakness of the interosseous muscles, specifically the adductor of the small finger.

On physical examination, one will often note weakness of interosseous muscles, atrophy of the FDI, and reduced sensation in the ulnar nerve territory in the hand. One may also find a Froment's sign indicating weakness of the adductor pollicis and the FDI (65). A Tinel's sign can often be noted at the elbow, but this is nonspecific and can be seen in a number of normal healthy individuals.

Because sensory conduction is difficult to reliably record across the elbow, most electromyographers will rely upon motor conduction studies of the ulnar nerve (56). There are a number of technical elements to keep in mind when performing these studies. First, it is advisable to record from both the ADM and the FDI at the same time, utilizing two channels of the EMG instrument. Although each muscle has similar sensitivity for detecting ulnar neuropathy at the elbow, there is not a complete overlap and sometimes one muscle will demonstrate conduction block when the other one does not (66). Stimulation usually occurs at the wrist, below the elbow, and above the elbow. When stimulating across the elbow, one should have the elbow in a flexed position with a roughly 70- to 90-degree angle. This is important because it stretches the nerve through the ulnar groove. If the elbow is not bent, the nerve is still long enough to accommodate elbow flexion but is redundant upon itself; therefore, surface measurement across the skin will underestimate the true distance and the calculated conduction velocity will be too slow.

There has been considerable discussion in the literature about the appropriate distances to use between the above and below elbow stimulation sites. Earlier literature suggested that in general one should have at least 10 cm of distance between stimulation sites (67). However, this was based upon measurements of error in the 1970s when measuring latencies on equipment using much older technology. Similar studies have now been repeated utilizing modern digital equipment (68), and this has demonstrated that a 6-cm distance should usually be sufficient and would have error similar to the 10-cm distance 30 years ago.

When performing ulnar motor conduction studies, one must be aware of the potential of Martin-Gruber anastomosis. This anastomosis is said to be present in 15% to 20% of individuals and typically involves fibers crossing from the median nerve to the ulnar nerve in the proximal forearm (69). At times, the fibers can originate from the anterior interosseous nerve rather than from the main branch of the median nerve. In the presence of Martin-Gruber anastomosis, one will record a normal large amplitude response from the ADM and FDI when stimulating the ulnar nerve at the wrist. However, while stimulating the ulnar nerve at the elbow, one will note a decreased amplitude response because one is stimulating only the ulnar nerve fibers and not those that cross in the proximal forearm. To the inexperienced electromyographer, this can masquerade as conduction block in the proximal forearm and can result in an erroneous diagnosis. The hint of a Martin-Gruber anastomosis rather than ulnar neuropathy in the forearm or elbow is that this drop in amplitude occurs between wrist and below elbow and not across

the elbow. The presence of this anomalous innervation can be proven by stimulating the median nerve at the elbow and recording from the ADM and FDI muscles; when a crossover exists, a sizable response can be recorded from these usually ulnar innervated muscles (70).

After recording ulnar conduction motor studies across the elbow, one will want to decide whether these are normal or not. There have generally been two ways to do this. Many authors advocate comparing ulnar conduction across the elbow to that recorded in the forearm. However, this comparison is flawed in that it assumes that ulnar conduction in the forearm is unaffected by a neuropathy proximally at the elbow (66). Unfortunately, this is not the case since with motor axon loss there is distal slowing due to preferential loss of the faster conducting fibers. As a result, comparison between the two segments is not valid. The other method for determining whether the conduction is normal is to compare the velocity to reference values. This has been shown to be preferable in terms of sensitivity and specificity (66). Our laboratory uses a reference value of 48 m/s as a lower limit of normal.

When there is concern for ulnar neuropathy at the elbow, it is frequently useful to perform ulnar “inching” studies. These studies involve stimulation of the ulnar nerve at 2-cm increments across the elbow looking for any focal slowing or conduction block. Latency differences exceeding 0.7 ms or amplitude differences exceeding 10% are suggestive of a focal lesion (71). It is preferable to see both latency and amplitude changes as well as changes in morphology to be certain of a focal lesion. Because the distances are small, and the error in measurement is large as a percentage, one should not consider the conduction velocity of inching studies in m/s but rather look at the established reference values ( $\leq 0.7$  ms) for latency differences across 2 cm.

Ulnar sensory conduction studies can be useful at times. When stimulating at the wrist and recording at the small finger, responses are usually small in amplitude or absent. It is difficult to reliably and consistently record ulnar sensory conduction across the elbow recording at the small finger. The response from the dorsal ulnar cutaneous nerve should be affected to a similar degree as the ulnar sensory response to the small finger.

Needle EMG should generally be performed in patients referred for ulnar neuropathy at the elbow including the ADM, FDI, and the flexor digitorum profundus. Remember, however, that the FDP is often spared in ulnar neuropathy at the elbow. When there are abnormalities in the ulnar innervated hand muscles, it is important to check non-ulnar innervated C8/T1 muscles to look for root or plexus lesions that might mimic an ulnar neuropathy. Generally, it is useful to check APB and extensor indicis proprius (EIP) in these situations.

### Radial Nerve at the Humerus

Radial nerve entrapments in the absence of trauma are much less common than entrapments of the median or ulnar nerves in the upper limb. This is in contrast to traumatic neuropathies where radial nerve injuries are more common due to the

proximity of the nerve to the humerus as it traverses along the spiral groove. The radial nerve is most typically affected along the spiral groove of the humerus, after the nerve has given branches to the triceps and the anconeus muscles but before it gives branches to the brachioradialis and the finger and wrist extensors. The site of the lesion is also proximal to the division of the nerve into superficial and deep branches (the deep radial nerve was formerly known as the posterior interosseous nerve) (72).

Patients typically present with symptoms of weakness when opening their hand and extending their wrist. They also report weak grip strength since grip is weaker with the wrist in flexion than it is with an extension. A strong grip requires wrist extension to produce a tenodesis effect on the long finger flexors. Patients will also report numbness in the radial distribution on the dorsum of the hand with a proximal radial neuropathy.

On physical examination, the primary finding on strength testing will be weakness of wrist and finger extension (73). There are, however, several special points to keep in mind when examining the patient with possible radial neuropathy. First, it is difficult to isolate the brachioradialis muscle, which is the first muscle supplied after the spiral groove, on manual muscle testing. It is best to test this muscle with the forearm in the neutral position and to flex the elbow while palpating and observing the brachioradialis muscle visually. Although the biceps and other elbow flexors are strong enough to substitute for the brachioradialis, one can usually palpate or visually appreciate a side-to-side difference when this muscle is weak. Secondly, one should take special care in examining finger extension. The extensor digitorum and other finger extensors supplied by the radial nerve primarily produce extension at the MCP (metacarpal phalangeal) joints. It is the ulnar innervated lumbricals and interossei that contribute to extension at the interphalangeal (IP) joints. As a result, extension of the fingers at the proximal interphalangeal joint (PIP) and distal interphalangeal joint (DIP) may be intact even with a complete radial neuropathy. Finally, one should be aware that when a patient has a radial neuropathy and weak finger extension that testing finger abduction (i.e., the interosseous muscles) will produce apparent weakness. This is not because of true muscle weakness but rather because testing finger abduction while the MCP joints are in a flexed position produces much less force than when they are fully extended. For this reason, it is important to have the patient lay his or her hand on a table or a book to complete testing of interosseous muscle function.

Physical examination will also usually show reduced sensation in the radial distribution of the hand and an absent brachioradialis muscle stretch reflex. Since the lesion is commonly distal to the branch supplying the triceps, the reflex at the triceps is typically intact.

In cases of radial neuropathy, needle EMG is often more useful than nerve conduction studies. Both recording and stimulation of the radial nerve for motor conduction studies can be problematic. Recording of the radial motor response

is typically achieved with surface electrodes placed over the EIP muscle. This is sometimes satisfactory but does suffer from the problem that other forearm muscles in the posterior compartment also contribute to this response via volume conduction. At times, some electromyographers will use needle recording to avoid volume conduction. While this does allow greater accuracy of measurement of latencies, it is less helpful for determining the CMAP amplitudes. With needle electrode recording, the amplitudes of motor responses are much more variable and dependent upon precise needle placement. Thus, needle recording should not be used for estimating how many axons are available in the nerve.

Stimulation, while relatively easily achieved in the distal forearm, is more difficult to achieve at the elbow and arm. It is difficult to obtain reliable consistent supramaximal responses at the spiral groove or proximally at the axilla. Probably the most useful setting for motor conduction studies in the assessment of radial neuropathy, is to evaluate the surface amplitude for the EIP with stimulation of the nerve in the distal forearm. This amplitude has been shown to correlate with the prognosis in radial neuropathy (74). Radial sensory responses are useful to evaluate for evidence of sensory axon loss and to evaluate whether the lesion is proximal to the branching of the radial nerve into superficial and deep branches. However, one generally does not stimulate the radial nerve proximally while recording sensory responses distally in the hand.

Needle EMG is usually the most useful electrodiagnostic assessment. One should generally consider studying the triceps muscle to look for evidence of denervation. If there is denervation in this muscle, then it is usually wise to proceed proximally to the deltoid muscle, which is also innervated by the posterior cord of the brachial plexus. If this is abnormal as well, then a broader evaluation of the limb is clearly indicated. Distally, it is useful to study the brachioradialis muscle since this is the first muscle to be innervated after the spiral groove (the anconeus muscle is innervated by the same branch that supplies the medial head of the triceps). The other muscles in the forearm that are useful to study include the extensor carpi radialis, extensor digitorum, and the extensor indicis proprius. It has been demonstrated that two of the more useful prognostic signs in radial neuropathy are presence or absence of a radial motor response to the EIP and the degree of recruitment noted in the brachioradialis muscle (74).

### Fibular Neuropathy

The fibular nerve (the preferred name for the nerve formerly known as peroneal) (72) is the most commonly affected nerve in the lower limb. It is particularly vulnerable to pressure as it crosses just behind the fibular head near the knee. It can also be affected by prolonged knee flexion or squatting as in prolonged labor and in those with occupations requiring prolonged squatting, such as strawberry pickers. This is the most common lower limb nerve injury in athletes (75).

The most common symptom of fibular neuropathy is weakness of dorsiflexion, presenting with foot slap or dragging

of the foot when walking (76). Patients also have sensory loss over the dorsum of the foot but rarely is this a prominent or presenting complaint.

Electrodiagnostic assessment generally includes motor and sensory conduction studies as well as needle EMG in the lower limb (77). Motor nerve conduction studies are often performed with recording over the extensor digitorum brevis (EDB) muscle. The EDB muscle is useful when studying the fibular nerve in the leg region, and it provides a conduction velocity between the fibular head and the ankle. On the other hand, the EDB is not a functionally useful muscle, and in moderately severe fibular neuropathies, or in polyneuropathies, the response may be absent. Thus, it is wise to record from both the EDB and the tibialis anterior (TA) muscles at the same time. The TA has the advantage of being a functionally more important muscle, and it may at times be present when the EDB is absent (78).

Sensory responses can be recorded from the superficial fibular nerve. This is helpful to distinguish between a proximal L5 root lesion (in which sensory conduction should be normal) and a more distal fibular nerve lesion. However, it is usually not otherwise helpful for localization. This response can also at times be misleading since a selective deep fibular nerve lesion will spare the superficial fibular sensory response.

Needle EMG can be very helpful in localization of fibular nerve lesions. It is usually helpful to study the TA and fibularis longus (formerly peroneus longus) muscles to evaluate both the deep and superficial branches. In order to exclude a more proximal lesion, one studies the short head of the biceps femoris since this muscle is supplied by the fibular division of the sciatic nerve proximal to fibular head. If this muscle is abnormal, then a wider examination of the lower limb is indicated. The EDB muscle can be studied with needle EMG but has a high frequency of false-positive results (28). It is also often useful to study tibial innervated muscles in the leg to exclude a more proximal sciatic lesion or a proximal root lesion.

Prognosis of fibular nerve lesions in large part is determined by both the amplitude of the motor responses and by the degree of motor unit recruitment in the TA muscle (78). Those with good recruitment in TA and present CMAP responses in TA and EDB generally do quite well.

### Tibial Nerve

Neuropathy affecting the tibial nerve is relatively rare compared to the other nerve lesions discussed above. This is likely related to the relatively protected position of the tibial nerve within the leg and foot. Moreover, the fascicular anatomy of the tibial nerve is such that it has many small fascicles that are resistant to injury (79). In comparison, the fibular nerve is made up of a few larger fascicles that are more susceptible to entrapment and trauma as well as stretching (79). The tibial nerve can occasionally be injured at the ankle. It is relatively common to have posttraumatic tibial neuropathy at the ankle after calcaneal fractures or other foot injuries. Much

more controversial, however, is the possible diagnosis of tarsal tunnel syndrome.

Patients with tibial neuropathy at the ankle can present with numbness or paresthesias in the sole of the foot (80). They may have predominant symptoms in either the lateral or medial plantar nerve distribution or occasionally in the calcaneal nerve distribution. As noted above, this can occur after trauma to the ankle or foot but may also be occasionally seen without history of injury. The etiology of nontraumatic tarsal tunnel syndrome is unclear. Some studies have shown that varicose veins, accessory muscles, or other space occupying lesions within the tarsal tunnel may be noted in these patients based on MRI examinations (81,82). Other investigators hypothesize that the hyperpronated foot, especially in runners, can predispose the tarsal tunnel syndrome, but this is more controversial.

There are several nerve conduction studies that can be performed to evaluate for possible tarsal tunnel syndrome (80,83). Motor conduction studies can be performed to muscles supplied by the medial and the lateral plantar nerves. One stimulates the tibial nerve at the ankle and records from the abductor hallucis and the abductor digiti quinti pedis at the same time. There are reference values for these two muscles in the literature, but one must be especially careful about temperature control since cold feet will markedly prolong the distal latencies. These motor studies are reported to be less sensitive than CNAP studies in the diagnosis of tarsal tunnel syndrome (84).

One can also perform CNAPs of the medial and lateral plantar nerves in the foot (85). This involves stimulation of the medial and lateral plantar nerves on the sole of the foot, recording proximally just above the medial malleolus. This is a CNAP rather than an SNAP since one is in part activating motor axons antidromically in addition to the orthodromic sensory potentials. Reportedly, these studies are more sensitive for demonstrating abnormalities than motor nerve conduction studies. However, these CNAP responses are usually quite small and often difficult to obtain. Thus, absence of a response is not diagnostic by itself. An asymmetrically delayed latency is more suggestive of a diagnosis of tarsal tunnel syndrome.

Needle EMG of intrinsic foot muscles can also be useful to assess for tibial neuropathy at the ankle. Some authors believe that tarsal tunnel syndrome can be a primarily axonal injury and thus EMG may be more useful at detecting this axon loss than the nerve conduction studies (86). This point, however, is not universally accepted. Needle EMGs are usually performed on a medial plantar innervated muscle such as the abductor hallucis and a lateral plantar innervated muscle such as one of the interossei. The FDI muscle can be used, but there is a high incidence of this muscle being jointly innervated by the deep fibular nerve (87). Thus, it is preferable to study the second dorsal interosseous muscle, between the second and third metatarsal bones. One must be cautious in interpreting findings on needle EMG in the intrinsic foot muscles since some studies have demonstrated a high incidence of false-positive results in

otherwise healthy individuals (28). The abductor hallucis and interosseous muscles are less likely to show abnormalities than the EDB. However, one should still be cautious in interpreting mild or subtle changes.

The author believes that nontraumatic tarsal tunnel syndrome is a very rare condition and has personally seen less than five convincing nontraumatic cases after having done more than 10,000 electrodiagnostic studies!

### Traumatic Neuropathies

Traumatic injury to peripheral nerves results in considerable disability across the world. In peacetime, peripheral nerve injuries commonly result from trauma due to motor vehicle accidents and less commonly from penetrating trauma, falls, and industrial accidents. Of all patients admitted to level I trauma centers, it is estimated that roughly 2% to 3% have peripheral nerve injuries (88,89). If plexus and root injuries are also included, the incidence is about 5% (88).

In the upper limb, the nerve most commonly reported injured is the radial nerve, followed by ulnar and median nerves (88,89). Lower limb peripheral nerve injuries are less common, with the sciatic most frequently injured, followed by fibular, and rarely tibial or femoral nerves.

Seddon has used the terms “neurapraxia,” “axonotmesis,” and “neurotmesis” to describe peripheral nerve injuries (90). Neurapraxia is a comparatively mild injury with motor and sensory loss but with no evidence of wallerian degeneration. The nerve conducts normally distally. Focal demyelination and ischemia are thought to be the etiologies of conduction block. Recovery may occur within hours, days, weeks, or up to a few months. Axonotmesis is commonly seen in crush injuries, nerve stretch injuries (such as from motor vehicle accidents and falls), or percussion injuries (such as from blast wounds). The axons and their myelin sheaths are broken, yet the surrounding stroma (i.e., the Schwann tubes, endoneurium, and perineurium) is at least partially intact. Degeneration occurs, but subsequent axonal regrowth may proceed along endoneurial tubes if they are sufficiently preserved. Recovery ultimately depends upon the degree of internal disorganization in the nerve as well as the distance to the end organ. Neurotmesis describes a nerve that has been either completely severed or is so markedly disorganized by scar tissue that axonal regrowth is impossible. Examples are sharp injury, some traction injuries, and percussion injuries or injection of noxious drugs. Prognosis for spontaneous recovery is extremely poor without surgical intervention.

Optimal timing of electrodiagnostic studies will vary according to clinical circumstances. For circumstances in which it is important to define a lesion very early, initial studies at 7 to 10 days may be useful at localization and separating conduction block from axonotmesis. On the other hand, when clinical circumstances permit waiting, studies at 3 to 4 weeks postinjury will provide much more diagnostic information, because fibrillations will be apparent on needle EMG. Finally, in cases where a nerve lesion is surgically confirmed and needle EMG is used only to document

**FIGURE 4-15.** Findings on motor nerve conduction with stimulation above and below the site of the lesion. Neurapraxia cannot be differentiated from axonotmesis or neurotmesis at day 1 but can be differentiated at day 10, after wallerian degeneration has occurred. The extent of axon loss can be determined by the CMAP amplitude obtained with stimulation distal to the lesion after day 10.

recovery, initial studies at a few months postinjury may be most useful.

Changes may be seen in the CMAP, late responses (F and H waves), SNAP, and needle EMG. Each of these studies has a somewhat different time course, which should be understood in order to evaluate peripheral nerve injury; they will also vary according to the severity of nerve injury.

In purely neurapraxic lesions, the CMAP will change immediately after injury, assuming one can stimulate both above and below the site of the lesion (Fig. 4-15). When recording from distal muscles and stimulating distal to the site

of the lesion, the CMAP should be normal because no axonal loss and no wallerian degeneration have occurred. Moving the site of stimulation proximal to the lesion will produce a smaller or absent CMAP, as conduction in some or all fibers is blocked. In addition to conduction block, partial lesions also often demonstrate concomitant slowing across the lesion. This slowing may be due to either loss of faster conducting fibers or demyelination of surviving fibers.

Electrodiagnostically, complete axonotmesis and complete neurotmesis cannot be differentiated, because the difference between these types of lesions is in the integrity of

the supporting structures, which have no electrophysiological function. Thus, these lesions can be grouped together as axonotmesis for the purpose of this discussion. Immediately after axonotmesis and for a “few days” thereafter, the CMAP and motor conduction studies look the same as those seen in a neurapraxic lesion. Nerve segments distal to the lesion remain excitable and demonstrate normal conduction, whereas proximal stimulation results in an absent or small response from distal muscles. Early on, this picture looks the same as conduction block and can be confused with neurapraxia. Hence, neurapraxia and axonotmesis cannot be distinguished until sufficient time for wallerian degeneration in all motor fibers has occurred, typically about 9 days postinjury (91).

After enough time has passed for wallerian degeneration to occur, the amplitude of the CMAP elicited with distal stimulation will fall. This starts at about day 3 and is complete by about day 9 (91). Thus, in complete axonotmesis at day 9, one has a very different picture from neurapraxia. There are absent responses both above and below the lesion. Partial axon loss lesions will produce small-amplitude motor responses, with the amplitude of the CMAP roughly proportional to the number of surviving axons.

F waves may change immediately after the onset of a neurapraxic lesion. In complete conduction block, responses will be absent. However, in partial lesions, changes can be more subtle, because F waves are dependent upon only 3% to 5% of the axon population to elicit a response (2). Thus, partial lesions may have normal minimal F-wave latencies and mean latencies, with reduced or possibly normal penetrance. Although F waves are conceptually appealing for detecting proximal lesions (e.g., brachial plexopathies), only in a few instances do they truly provide useful additional or unique information. They are sometimes useful in very early proximal lesions when conventional studies are normal because stimulation does not occur proximal to the lesion.

The SNAP and CNAP show changes similar to the CMAP after focal nerve injury. With neurapraxia, there is focal conduction block at the site of the lesion, with preserved distal amplitude. Immediately after axonotmesis and for a few days thereafter, the SNAP looks the same, as with a neurapraxic lesion. Nerve segments distal to the lesion remain excitable and demonstrate normal conduction, whereas proximal stimulation results in an absent or a small response. It takes slightly longer for sensory nerve studies to demonstrate loss of amplitude than for motor studies, that is, 11 days versus 9 days, due to the earlier failure of NMJ transmission compared with nerve conduction.

On needle EMG, in neurapraxic lesions, the most apparent changes will be in recruitment. These occur immediately after injury. In complete lesions (i.e., complete conduction block), there will be no MUAPs. In incomplete neurapraxic lesions, there will be reduced numbers of MUAPs firing more rapidly than normal (i.e., reduced or discrete recruitment). Because no axon loss occurs in neurapraxic injuries, there will be no axonal sprouting and no changes in MUAP morphology (e.g., duration, amplitude, or phasicity) at any time after injury.

With axonotmesis, needle EMG will demonstrate fibrillation potentials and positive sharp waves a number of days after injury. The time between injury and onset of fibrillation potentials will be dependent in part upon the length of the distal nerve stump. When the distal nerve stump is short, it takes only 10 to 14 days for fibrillations to develop. With a longer distal nerve stump (e.g., ulnar-innervated hand muscles in a brachial plexopathy), 21 to 30 days is required for full development of fibrillation potentials and positive sharp waves (92). Thus, the electrodiagnostic medicine consultant needs to be acutely aware of the time since injury so that severity is not underestimated when a study is performed early after injury, and also that development of increased fibrillation potentials over time is not misinterpreted as a worsening of the injury.

Fibrillation potential size decreases over time since injury. Kraft (93) has demonstrated that fibrillations initially are several hundred microvolts in the first few months after injury. However, when lesions are more than 1 year old, they are unlikely to be more than 100  $\mu$ V in size.

Fibrillations may also occur after direct muscle injury as well as nerve injury. Partanen and Danner (94) have demonstrated that patients after muscle biopsy have persistent fibrillation potentials starting after 6 to 7 days and extending for up to 11 months. In patients who have undergone multiple trauma, coexisting direct muscle injury is common and can be potentially misleading when trying to localize a lesion.

When there are surviving axons after an incomplete axonal injury, remaining MUAPs are initially normal in morphology but demonstrate reduced or discrete recruitment. Axonal sprouting will be manifested by changes in morphology of existing motor units. Amplitude will increase, duration will become prolonged, and the percentage of polyphasic MUAPs will increase as motor unit territory increases (95,96). In complete lesions, the only possible mechanism of recovery is axonal regrowth. The earliest needle EMG finding in this case is the presence of small, polyphasic, often unstable MUAPs previously referred to as “nascent potentials.” (This term is now discouraged because it implies an etiology; it is preferred to simply describe the size, duration, and phasicity of the MUAP.) Observation of these potentials is dependent upon establishing axon regrowth as well as new NMJs, and this finding represents the earliest evidence of reinnervation, usually preceding the onset of clinically evident voluntary movement (95). These potentials represent the earliest definitive evidence of axonal reinnervation in complete lesions. When performing the examination looking for new MUAPs, one must be sure to accept only “crisp,” nearby MUAPs with a short rise time, because distant potentials recorded from other muscles can be deceptive.

Determining the pathophysiology of a peripheral nerve traumatic injury can help with estimating prognosis. Those injuries that are completely or largely neurapraxic have a good prognosis for recovery within a few months (usually up to 3 months postinjury). Resolution of ischemia and remyelination should be complete by this time.

In axonotmesis, recovery will depend upon axonal sprouting and regeneration. Hence, there will be some early recovery followed possibly by a later recovery if or when regenerating axons reach their end organs. The amplitude of the CMAP provides some guide to prognosis. In facial nerve lesions, it has been demonstrated that patients with CMAP amplitudes 30% or more of the other side have an excellent outcome, those with 10% to 30% have good but not always complete recovery, and those with <10% have a poor outcome (97). There is some evidence, however, that outcomes are better in peripheral nerves than in the facial nerve (74,78).

Complete axonotmesis and neurotmesis have the worst prognosis. Recovery depends solely upon axonal regeneration, which may or may not occur, depending upon the degree of injury to the nerve. In many cases of complete axon loss, it is not possible to know the degree of nerve injury except by surgical exploration with or without intraoperative recording or looking for evidence of early reinnervation after the lesion. As a consequence, it is often recommended to wait 2 to 4 months and look for evidence of reinnervation in previously completely denervated muscles near the site of the lesion (98,99). Those lesions that have some spontaneous recovery are usually treated conservatively, because operative repair is unlikely to improve upon natural recovery. Those with no evidence of axonal regrowth may have operative exploration with possible grafting.

## Radiculopathy

Radiculopathy is another very common reason for assessment in the electrodiagnostic laboratory. The electrodiagnostic evaluation can be useful in assessing for the presence of radiculopathy, localizing the lesion, and exploring other possible diagnoses that may be confused with root disease (11).

The typical clinical presentation of radiculopathy is well covered in other chapters. Most commonly, it involves pain starting from the neck or the back and extending into the upper or lower limb. It is often accompanied by sensory symptoms and sometimes by weakness. Physical examination may show weakness, depressed reflexes, and positive relevant provocative signs (such as straight leg raise test or Spurling's sign). Although sensory loss is often found, this is not as predominant or as well circumscribed as it might be in peripheral nerve lesions.

The etiology of radiculopathy can be multifactorial (100). There are certain structural lesions such as disk protrusions and bony lesions that can press upon the root. However, the electrodiagnostic medical consultant should keep in mind that there are other causes of radiculopathy as well. Neoplasms either at the root or at the spinal cord level can look like a radiculopathy. There are metabolic or inflammatory lesions such as diabetes or vasculitis, which can produce a radiculopathy without significant structural changes apparent on imaging studies. There are also infectious causes such as herpes zoster that can affect the roots. Thus, not all radiculopathies are caused by disk protrusion.

In general, the most useful electrodiagnostic assessment in radiculopathy is needle EMG. There have been studies suggesting how many muscles should be studied in a limb when assessing for possibly radiculopathy (101,102). It is generally preferable to examine at least five muscles in the lower limb plus paraspinal muscles and five muscles in the upper limb plus paraspinal muscles to reach a high degree of sensitivity on needle EMG. When the paraspinal muscles are not available, such as after surgical intervention, then one should increase the number of limb muscles to eight to achieve a similar degree of sensitivity.

The selection of muscles should be tailored to each patient depending on which root level is in question. For example, if the patient's symptoms are more in the C6 distribution, one should include more C6 level muscles and perhaps fewer muscles at the C8 or T1 level. When symptoms are nonspecific, then one should design an electrodiagnostic evaluation that includes multiple roots and multiple peripheral nerves within the limb. Examples of commonly used screens are given below:

Upper Limb Radiculopathy Screen	Lower Limb Radiculopathy Screen
Deltoid	Vastus medialis
Biceps	Tensor fascia lata
Pronator teres	Tibialis anterior
Triceps	Medial gastrocnemius
FDI	Biceps femoris long head
Cervical paraspinal muscles	Lumbar paraspinal muscles

The key to diagnosing radiculopathy is to find evidence of denervation in at least two muscles within a single myotome (the distribution of muscles supplied by a single root) but supplied by different peripheral nerves (11). For example, evidence of denervation in the TA and fibularis longus muscles would not be sufficient to diagnose an L5 radiculopathy because both muscles are within the common fibular nerve distribution. However, the same changes in the TA and tensor fascia lata would be much more suggestive of a root lesion.

It is important to consider carefully which types of electrodiagnostic findings are sufficient to be diagnostic. Most electromyographers would agree that evidence of the following potentials in a myotomal distribution would be diagnostic:

- Fibrillation potentials
- Positive sharp waves
- CRD
- Fasciculation potentials

It is more controversial as to which motor unit changes can be considered diagnostic. If there are very large amplitude, long duration, polyphasic MUAPs in a myotomal distribution, then one might interpret the study as suggestive of chronic radiculopathy with reinnervation. However, one should not

diagnose a radiculopathy based solely upon increased numbers of polyphasic MUAPs, since these are often found in otherwise healthy individuals in many muscles.

The paraspinal muscles can be very useful to help localize a lesion to the root level, since these muscles are supplied by the posterior primary ramus of the root. Evidence of denervation in these muscles, combined with the limb muscles, is highly suggestive of root pathology. At the same time, however, one must be cautious in interpreting paraspinal findings. Some authors have reported the presence of fibrillation potentials and positive sharp waves in otherwise healthy individuals in the lumbar and cervical paraspinal muscles, with an increasing frequency with age (27,103). Moreover, there are other causes for fibrillation potentials in the paraspinal muscles besides radiculopathy. For instance, myopathies, prior spine surgery, recent prior needle intervention, metastatic muscle lesions, and diabetes can all cause paraspinal abnormalities without significant radiculopathy. Moreover, the paraspinal muscles are not root localizing since most of the muscles are multisegmentally innervated (104). Localization is primarily achieved through analysis of limb muscle findings.

In addition to needle EMG, H waves can be useful in diagnosing S1 radiculopathies. H waves are similar in their physiology to the ankle jerk, except that stimulation occurs proximal to the muscle spindles. The primary advantage of H waves in the assessment of radiculopathy is that they will detect sensory axon loss, conduction block, and demyelination in the root, whereas needle EMG only detects loss of motor axons (19). Side-to-side differences in H-wave latency exceeding 1.2 to 1.5 ms are likely abnormal. One should be cautious, however, in interpreting H waves since any lesion along the pathway (from the soleus muscle to the S1 root) can cause abnormalities in this response. Moreover, H-wave abnormalities do not indicate chronicity, and these responses can be abnormal in very acute or very chronic or old root lesions.

Sensory responses should usually be normal in root pathology since here the lesion is proximal to the DRG. F waves are generally of little use in evaluation of radiculopathy. It is believed that since muscles are supplied by more than one root, the responses traverse more than one root proximally, and a single intact root can produce normal F-wave latencies.

The electrodiagnostic medical consultant is often asked about the sensitivity of needle EMG in comparison to imaging studies. Generally, the EMG is considered to have sensitivity for radiculopathy in the range of 70% to 80% compared to clinical presentation (101,105,106). This is in contrast to imaging studies that are often reported with sensitivities exceeding 90%.

Sensitivity, however, is not the only figure of merit. One should be equally or even more concerned about specificity, that is, the ability to detect absence of disease and to avoid false-positive findings (59). Specificity of needle EMG, using the approach discussed above, is excellent, likely exceeding 95%. If one were to make a diagnosis based solely upon paraspinal findings or a few polyphasic motor units, the speci-

ficity would be less. By contrast, the specificity of imaging is much lower. Many studies have reported imaging specificities in the 60% to 70% range, with a false-positive rate of 30% to 40% (107). Thus, a primary advantage of needle EMG is the high specificity it offers in comparison to imaging studies.

### Plexopathy

The assessment of brachial and lumbosacral plexopathy is one of the more challenging aspects of the electrodiagnostic examination (108). An important and elementary requirement is that the electrodiagnostic physician be well acquainted with the anatomy of the brachial plexus or in some cases, the lumbosacral plexus. In this author's experience, it is usually necessary for the electrodiagnostic consultant to be able to draw the brachial plexus with all branches in less than a minute in order to have a sufficient working knowledge of the anatomy. There are Web sites available to help with drawing the anatomy easily (e.g., [http://www.ama-assn.org/ama1/pub/upload/mm/15/brachial\\_plex\\_how\\_to.pdf](http://www.ama-assn.org/ama1/pub/upload/mm/15/brachial_plex_how_to.pdf)). Although one could look up the brachial plexus online or in text books, without this solid working knowledge, one will not think of patterns that represent plexus lesions and will potentially miss some important diagnoses.

The etiologies of brachial plexopathy are varied. Most common is trauma, both in children and in adults. Motorcycle crashes, motor vehicle crashes, falls, and industrial injuries account for the great majority of brachial plexus lesions. It is estimated that 2% to 3% of patients coming to level 1 trauma centers have a brachial plexus injury (88). There are other causes of brachial plexus lesions such as neuralgic amyotrophy, radiation plexitis, tumor invasion, true neurogenic thoracic outlet syndrome, and others.

Lumbosacral plexopathies are much less common. Traumatic lumbosacral plexopathies occur in less than 1% of patients with pelvic fractures (109). Moreover, the lumbosacral plexus is less affected by other diseases than the brachial plexus. The placement of the lumbosacral plexus within the pelvis offers a great deal of protection compared to the relatively vulnerable brachial plexus in the upper limb and shoulder. The lumbosacral plexus nevertheless can be affected by trauma, radiation plexitis, diabetes, and neuralgic amyotrophy, all of which are rare.

Patients with plexopathy can present with a varied presentation. Typically, there is pain in the limb (but not the spine) and there are sensory symptoms in the limb. Occasionally, patients present with a plexopathy after breast cancer and subsequent radiation; those with radiation plexitis typically have upper trunk distribution paresthesias, whereas those with tumor invasion present with lower trunk painful lesions (34). Physical examination is usually remarkable for weakness, significant sensory loss outside of a single peripheral nerve distribution, and reduced reflexes.

Sensory nerve conduction studies can be very useful to differentiate plexus lesions from more proximal root pathology. As has been discussed above, root lesions will have normal SNAPs, whereas plexus lesions (distal to the DRG) will have

abnormal or absent sensory responses. This fact can be used to screen the brachial plexus. For example, one can evaluate the upper trunk through the use of median and radial nerve sensory testing to the thumb (C6). The middle trunk can be evaluated by stimulating the median nerve and recording from the long finger (C7), and the lower trunk can be evaluated by testing the ulnar sensory potential to the small finger (C8). If these are all intact, it would argue strongly against a brachial plexus lesion affecting the upper, middle, or lower trunk. Similarly, one can use SNAPs in the lower limb to evaluate for peripheral nerve or plexus lesions versus root pathology.

The reader should be aware of a rather unique setting in which the presence of normal sensory potentials is a very poor prognostic sign. When a patient is evaluated for brachial plexopathy, at times they will have complete root lesions such as root avulsion rather than a more distal brachial plexus lesion. When the roots have been avulsed from the spinal cord, this is a very poor prognosis, and there is essentially no likelihood of recovery. In this setting, the SNAPs will be normal because the dorsal root ganglia have been avulsed along with the plexus, and there is no subsequent degeneration of sensory axons. However, needle EMG will be consistent with complete denervation and no motor responses will be obtainable. In this case, presence of normal sensory potentials generally suggests root avulsion and a very poor prognosis for recovery, though these findings do not always agree with imaging studies (110).

Motor nerve conduction studies are also useful in the assessment of brachial plexopathy, particularly for prognosis. One can determine the degree of axon loss by recording from an affected muscle and stimulating the nerve distal to the lesion. For example, in the case of an upper trunk plexus lesion, one might stimulate the musculocutaneous nerve in the axilla and record from biceps. A large amplitude response here would indicate a rather good prognosis since the lesion does not have severe axon loss.

Needle EMG can also be helpful in diagnosing and localizing brachial plexopathy. These are usually very extensive evaluations. This author generally finds it helpful to draw out the plexus in question and can make sure that a muscle supplied by each of the significant branches off the plexus is tested on needle EMG. Paraspinal muscles are also very useful because abnormalities there will suggest a more proximal root lesion.

F-wave responses can be helpful early on in a possible brachial plexus lesion, before motor or sensory conduction studies have changed and before needle EMG shows abnormalities. Absence of F waves may indicate a proximal lesion particularly if distal conduction is intact. However, it should be remembered that an abnormality anywhere along the course of the F wave will produce an abnormal response. In the setting of more chronic pathology, it is rare that the F wave will show a unique abnormality that is not apparent on other nerve conduction studies or needle EMG.

### Polyneuropathies

The goal of electrodiagnostic evaluation in assessing peripheral polyneuropathies is to both detect abnormalities and classify

the neuropathy into one of six groups. One should also determine whether there are other lesions (such as spinal stenosis) that can produce similar clinical presentations.

There are generally six categories in which one can place peripheral polyneuropathies. These are well covered in other references (111). The six categories will be discussed briefly below.

### Uniform Demyelinating Neuropathies

Uniform demyelinating neuropathies are inherited neuropathies in which myelin is abnormal throughout the peripheral nervous system. Examples include Charcot-Marie-Tooth disease (type 1), Refsum's disease, Dejerine-Sottas disease, and others. Because of the diffuse abnormality of myelin, one sees diffuse nonsegmental changes. In these uniform demyelinating neuropathies, one sees diffuse slowing of nerve conduction velocities (without patchiness), prolonged distal latencies, and prolonged or absent F-wave responses. There is no conduction block or temporal dispersion. Generally, motor fibers are more affected than sensory fibers. Needle EMG can reveal mild evidence of distal denervation, but this is not as marked as the slowing that is apparent on nerve conduction studies.

### Segmental Demyelinating Neuropathies

Segmental demyelinating neuropathies are acquired neuropathies (not inherited) that present with patchy demyelination along the peripheral nervous system. Examples include Guillain-Barre syndrome, monoclonal gammopathies of undetermined significance, chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), multiple myeloma, and others. The hallmark of this category is patchiness of abnormalities. Generally, there are five findings seen on nerve conduction studies in this group including (a) prolonged distal latencies, (b) prolonged or absent F-wave responses, (c) patchy slowing (faster in some areas, slower in other areas of the same nerve), (d) conduction block, and (e) temporal dispersion. This can be differentiated from the inherited neuropathies mentioned above by the presence of patchy slowing, conduction block, and temporal dispersion. Needle EMG will often show patchy denervation in more severe cases. Motor findings are more prominent than sensory findings in these patients. Many of these patients will have sparing of sural SNAPs but relatively greater abnormalities noted in the upper limb sensory responses. Prognosis in these cases has been shown to correlate best with the distal CMAP amplitudes (112). When amplitudes are larger than 10% of the lower limit of normal at the nadir of the illness, prognosis is generally good.

### Sensory Neuropathy or Neuronopathy

Sensory neurons can be selectively affected at their cell bodies (neuronopathy) or axons (neuropathy). There are a variety of lesions that predominantly affect sensory nerves. At the cell body level, there is an entity that is known as dorsal root ganglionitis, or sensory neuronopathy. This represents death of the cell body within the DRG and subsequent loss of sensory axons. Most commonly, this is seen as a paraneoplastic presentation, but occasionally, autoimmune diseases can present with the same findings (113).

Selective loss of sensory axons distally can be seen in a variety of toxins such as B6 toxicity, cis-platin exposure, and others.

The hallmark of this category is the absence of SNAPs or reduction in their amplitudes. When these presentations are severe, one will be unable to obtain a sensory response anywhere in the limbs. In general, motor nerve conduction and needle EMG are normal as expected with selective involvement of sensory nerves.

### **Motor Greater than Sensory Axon Loss**

Motor greater than sensory neuropathies are rare. In evaluating these patients, one should be wary of other diseases that can present with similar findings such as motor neuron disease, NMJ disease, or myopathy. Selective motor neuropathies can be seen in acute porphyria, heavy metal exposure, and exposure to vinca alkaloids, amongst other conditions. Occasionally, inherited neuropathies (e.g., Charcot-Marie-Tooth disease type 2) also present this way.

The primary abnormality in this category is reduced amplitude or absent motor responses with relatively normal SNAPs. Needle EMG usually shows length-dependent evidence of denervation in the limb muscles with more distal muscles showing greater abnormalities than proximal limb muscles. There is usually no significant slowing of nerve conduction studies in this group, although mild slowing could be present due to loss of faster conducting fibers.

### **Motor and Sensory Axon Loss**

This is the most common presentation of polyneuropathy and has the greatest number of etiologies amongst all the categories. This group includes the majority of toxic exposures, paraneoplastic conditions, infectious diseases (such as HIV), and other etiologies. One sees reduced amplitude sensory and motor amplitudes on nerve conduction studies with relatively little slowing. Needle EMG also shows length-dependent evidence of denervation worse in the distal muscles of the limb. In many cases, the exact etiology of these polyneuropathies remains undetermined even after extensive investigation. Only about 60% of these patients will ultimately have an etiologic diagnosis.

### **Motor and Sensory Axon Loss and Demyelination**

There are two common diseases that present with motor and sensory axon loss and demyelination: diabetes and uremia. These two diseases present with a mixture of reduction of SNAP amplitudes, reduced amplitude CMAPs, mild to moderate slowing of conduction, and evidence of denervation worse distally in the limbs.

When evaluating possible polyneuropathy, it is reasonable to start by performing motor and sensory conduction studies and F waves in one upper limb and one lower limb. This author's approach is generally to perform the following nerve conduction studies: sural sensory, fibular motor, fibular F wave, ulnar sensory, ulnar motor, and ulnar F wave (the advantage of ulnar nerve studies is that it avoids possible misinterpretation

resulting from median neuropathy at the wrist). If the symptoms are primarily in the lower limb and the lower limb nerve conduction studies are normal, it may not be necessary to study the upper limb.

Needle EMG should be performed routinely because it is more sensitive at detecting motor axon loss than nerve conduction studies. The TA and soleus muscles are useful muscles, and occasionally, one may study an interosseous muscle in the foot. When there are abnormalities seen in the lower limb, other muscles should be studied in the lower limb as well as some upper limb muscles to determine whether this represents a distal greater than proximal gradient.

The electromyographer needs to be aware of the effects of temperature upon nerve conduction studies. If the limb is excessively cold, less than 32°C, it is generally preferable to warm up the limb with a hairdryer, warm water, or other method. The use of correction factors, particularly for correction across many degrees of temperature, is discouraged.

In writing the report, it is usually not possible to definitively indicate the cause of the polyneuropathy in the patient being studied. However, one can indicate the category as discussed above and include a differential diagnosis that fits with the clinical presentation.

### **Myopathy**

EMG can be very useful in the assessment of patients with possible muscle disease. Generally, patients presenting with a possible myopathy will primarily report symptoms of proximal weakness. They often report difficulty climbing stairs, difficulty brushing their hair or teeth, and at times difficulty with breathing or coughing. Some patients will have muscle pain or tenderness. If there are any sensory symptoms, then an alternative diagnosis should be considered. On examination, one will generally note proximal weakness greater than distal weakness. A Trendelenburg sign is often present and may be either compensated or uncompensated. Reflexes are usually preserved until late in the progression of the disease.

The diagnosis of myopathy depends upon multiple evaluations. First, the clinical presentation needs to be consistent with myopathy. In addition, laboratory values should usually show elevated muscle enzymes such as creatine kinase. Muscle biopsy is often important to arrive at a more definitive diagnosis in terms of what type of myopathy is present. Finally, EMG can demonstrate abnormalities that can help with determining the presence, activity, and sometimes help with diagnosis of the myopathy (114,115).

One should approach the patient with myopathy by studying only one side of the patient (right or left). This is important because many patients will have a subsequent muscle biopsy, and it is preferable to avoid histological examination of muscles that have had a recent needle EMG examination. Muscle trauma from the EMG needle can sometimes mimic changes from inflammation.

It is often helpful to study both proximal and distal muscles in the limb to look for a proximal greater than distal gradient since proximal muscles should be affected considerably more

than distal muscles. One major exception to this rule is myotonic dystrophy that presents with distal findings greater than proximal (116). Even though they are not easily biopsied, the EMG evaluation should usually include paraspinal muscles as they are very sensitive. It is also wise to include muscles that can be biopsied on the contralateral side such as quadriceps, biceps, or deltoid.

On needle EMG, many acquired myopathies and inherited dystrophies will be associated with fibrillations and positive sharp waves, especially when there is inflammation. It is hypothesized that inflammation induces segmental necrosis. As a result of this focal necrosis, distal portions of the muscle fibers are functionally denervated and fibrillate. When there is no inflammation, such as with chronic steroid myopathy (which produces selective type II fiber atrophy), needle EMG will be relatively normal at rest. In inflammatory myopathies, the presence of fibrillation potentials and positive sharp waves is suggestive of more active disease, whereas muscles studied in those with treated disease will often have no significant spontaneous activity (117,118). CRDs are commonly seen in myopathies, especially in chronic inflammatory myopathies, though they are not specific for muscle disease. As mentioned earlier, MUAPs in myopathies are generally small in amplitude, brief in duration, and sometimes polyphasic. They are recruited in an “early” pattern with many MUAPs firing, despite small amounts of force.

On nerve conduction studies, SNAPs should generally be normal without any significant slowing or changes in amplitude. On the other hand, CMAPs may be reduced in size, proportional to the degree of muscle fiber loss. Conduction velocity is usually preserved. At times, one will see unusual potentials in muscles that will help refine the diagnosis. For instance, the presence of myotonic discharges will indicate that the patient may have a myotonic syndrome such as myotonic dystrophy, myotonia congenita, acid maltase deficiency, or other rare diseases.

After the needle EMG has been completed, it is often helpful for the electromyographer to suggest some potential contralateral muscles for subsequent muscle biopsy. Generally, it is good to select a muscle with moderate disease. If one selects a muscle with very severe electrodiagnostic changes, often the muscle biopsy will be read as end-stage muscle disease and will offer little specificity as to the etiology.

It may be useful to repeat the EMG in inflammatory myopathies treated with steroids. In those patients with polymyositis who have initial recovery but later weakness, there is often a question as to whether this represents recurrence of the inflammatory disease or new steroid myopathy. In disease recurrence, one sees increased spontaneous activity such as fibrillation potentials and positive sharp waves (119). However, if a patient has steroid myopathy, which does not cause segmental necrosis or muscle fiber loss, one will see a relatively normal needle EMG in terms of both spontaneous activity and initially recruited MUAPs (120).

Critical illness myopathy is probably the most common myopathy seen in patients admitted to the hospital. This commonly coexists with critical illness polyneuropathy, but the

former has a better prognosis (121). Findings are not always pronounced but usually demonstrate small amplitude CMAPs, normal SNAPs (unless there is coexisting polyneuropathy), and proximal greater than distal needle EMG abnormalities. It is often difficult to examine MUAPs since these patients are often not alert enough to produce a muscle contraction. There are recently described techniques for direct muscle stimulation that have suggested that much of the weakness noted in the ICU is due to critical illness myopathy (122).

## Motor Neuron Disease

Motor neuron disease can have multiple presentations, which are well covered in other chapters in this textbook, the most common of which is amyotrophic lateral sclerosis (ALS). ALS is characterized by both upper and lower motor neuron loss as well as involvement of both bulbar and limb muscles. ALS usually starts off with focal weakness without any sensory loss and with little or no pain. The weakness can be in the distal upper or lower limb or, especially in the older individuals, in the bulbar musculature. Fasciculations are often noted by the patient and reported to the physician.

There are several symptoms and/or signs that make the diagnosis of ALS unlikely including presence of sensory symptoms such as numbness or tingling, presence of urinary incontinence, or deficits in extraocular muscles.

There are other variants of motor neuron disease in addition to ALS (123). Primary lateral sclerosis (PLS) presents with selective involvement of the corticospinal tracks in the brain and spinal cord. These patients have upper motor neuron syndromes without significant atrophy or evidence of lower motor neuron loss. They have a somewhat better prognosis than ALS but some eventually progress into ALS. Progressive bulbar palsy (PBP) starts off with weakness primarily in the bulbar muscles. Most commonly, patients present with slurring of speech or difficulty swallowing. This often quickly evolves into full blown ALS and has a worse prognosis than if the onset were in the limbs instead. Spinal muscular atrophy (SMA) is a predominantly lower motor neuron loss that has a slower disease progression and somewhat better prognosis than ALS. It does not have prominent upper motor neuron features. Monomelic amyotrophy looks like ALS clinically but is confined to one limb and has a much better prognosis. It usually has both upper and lower motor neuron features in one limb without any sensory changes.

With respect to ALS, physical examination usually shows weakness in either one limb or, as the disease becomes advanced, more diffusely. There is often dysphagia and slurring of speech, which are worrisome signs. There should be no significant sensory loss unless there is a coexisting lesion such as sensory polyneuropathy. Reflexes are typically brisk, consistent with the upper motor neuron involvement. However, at the same time, there is usually atrophy that suggests lower motor neuron loss.

When evaluating a patient with possible motor neuron disease, it is most fortunate for the patient if the electromyographer can identify some other (treatable) cause of the patient's

symptoms. At times, myopathies, NMJ diseases, cervical spinal stenosis, and multifocal motor neuropathy with conduction block (124) can all mimic ALS. In contrast to ALS, these are treatable lesions without rapid progression to death.

Nerve conduction studies are first performed to evaluate for polyneuropathy or to look for multifocal motor neuropathy with conduction block. It is generally useful to study one motor and one sensory nerve in an upper and lower limb, with multiple sites of stimulation, in addition to F waves. In ALS, these are usually normal except for potentially reduced amplitudes of the CMAPs. If there is conduction block, then other diagnoses should be considered.

Needle EMG is usually performed according to the diagnostic requirements of the El Escorial criteria (125). These criteria divide the body into four regions: bulbar, cervical, thoracic, and lumbosacral. The electromyographer should study muscles from each of these regions to look for evidence of denervation, fasciculation potentials, or reinnervation. Presence of abnormalities in three or four of these regions is consistent with a diagnosis of ALS. When only one or two regions are involved, then the diagnosis is only possible or probable. There is recent debate about how these criteria should be used and/or modified (126) and whether or not fasciculation potentials must be recorded to be diagnostic.

Examples of muscles that can be studied in patients with possible ALS include

Bulbar	Cervical	Thoracic	Lumbosacral
Tongue	Biceps	Paraspinal muscles	Vastus medialis
Facial muscles	Flexor carpi radialis		Tensor fascia lata
	First dorsal interosseous		Medial gastrocnemius

Muscles such as these are selected to give a sampling of multiple roots and multiple peripheral nerves to diffusely screen for motor neuron loss. The thoracic paraspinal muscles are especially important to study because they are commonly affected in motor neuron disease (127). Moreover, when abnormal, they help to exclude the presence of combined cervical and lumbar spinal stenosis, which could result in abnormalities in both the upper and lower limbs. Likewise, the bulbar muscles are very important because, when abnormal, they help to exclude spine disease as the cause of the patient's presentation.

When abnormalities are detected, the needle examination may need to be expanded beyond that summarized above. The primary finding on needle EMG is that of acute denervation, with positive sharp waves and fibrillations. Although fasciculation potentials are not required for a definitive diagnosis, their presence is much more suggestive of motor neuron disease than when they are absent. The presence of polyphasic, large-amplitude, long-duration MUAPs

is suggestive of chronic reinnervation and should be seen in the limbs as well as evidence of denervation. Often, reduced recruitment with rapid firing of MUAPs is one of the first findings in ALS. Since progressive motor neuron loss can often be compensated by distal sprouting, there may not be prominent fibrillation potentials early in the disease.

Generally, when evaluating the patient with motor neuron disease, it is preferable not to discuss the findings or even the differential diagnosis with the patient or in front of the patient unless he or she has already been discussing this with a referring physician. Getting into a discussion during the study often prompts questions that the electromyographer is not prepared to answer.

## REPORT WRITING

After the electrodiagnostic examination has been completed, one then writes the electrodiagnostic report. This usually includes several elements such as

- Identifying information (name, medical record number, date of birth, name of referring physician, name of examining physician, and date of study).
- Brief history and physical (enough to support your differential diagnosis but not so long as to repeat extensive notes from the medical record).
- *Electrodiagnostic data* should be presented in tabular form with pertinent findings listed in the tables. Most recent electrodiagnostic instruments can automatically prepare these reports in a word processing document, but the electromyographer should use caution when employing this feature. Because the instruments will automatically place cursors on all wave forms, at times the automated reports will give cursor information when no response is in fact present. The electromyographer should review these tables to make sure that they are accurate and that responses are listed as absent when they are unobtainable.
- Summary of findings (how you interpret the findings—for example, “there is evidence of acute denervation in the C7 myotome” or “there is slowing of median motor and sensory conduction across the wrist”). The physician should not repeat what is in the data tables in this section.
- The *impression or conclusion* should be succinct and should clearly address the referring physician's question. It should include whether the study was normal or abnormal, which diagnoses were ruled in, important diagnoses that were ruled out, pathophysiology, and prognosis when appropriate. This section should be able to stand alone, since some referring physicians will only read this part of the report. It should also give the side (right or left) and the pathophysiology (e.g., axon loss or demyelination). Sometimes, the electromyographer will not have a final diagnosis but will have a differential diagnosis, and this should be clearly stated in the impression (it is better to give a differential diagnosis than to simply guess what it might be).

- The study will sometimes be normal. In these cases, the electrodiagnostic medical consultant will want to report “There is no electrodiagnostic evidence of...” Other times, the electromyographer will have a different diagnosis than the referring diagnosis. In these cases, one should comment on the referring diagnosis as well as the diagnosis found during the study.

Guidelines for what should go in the report are available on the Web site of the American Association of Electrodiagnostic and Neuromuscular Medicine (<http://www.aanem.org/practiceissues/practiceguidelines/practiceguidelines.cfm>).

In most cases, one should assume that the patient may read the medical record, and take care in the use of wording that might be offensive or might be interpreted as derogatory (e.g., obese or argumentative).

## SUMMARY

In summary, the electrodiagnostic evaluation is critical to the understanding of nerve and muscle disease, to the management of peripheral nervous system disease, and to assessing prognosis for a variety of lesions that the physiatrist will encounter.

## ACKNOWLEDGMENTS

The author wishes to thank Paula Micklesen for the preparation of figures, Kevin Bleich for manuscript preparation, Dr. Leilei Wang for review of the manuscript, and Michelle Walter for her editing assistance.

# Human Walking

Walking is one of the most basic and ubiquitous forms of human motion. While studying gait, one can simply observe the world in motion. Airports and shopping malls are excellent places to watch walking. Observe the changes that occur based upon each person's gait speed, height, or age. Compare those who are carrying loads with those who are unfettered. And observe yourself walking in different surface conditions and hills and at different speeds. Which pattern causes fatigue and shortness of breath, and which muscles become fatigued? Building up this personal knowledge base will help the physician to evaluate complaints of walking difficulty and gather information that might clarify the problem.

The basic unit of walking is the *gait cycle*, which is typically recorded from the time one foot strikes the ground until that episode recurs and starts the next, repeating cycle. During one gait cycle, the body traverses a distance of one *stride* (Table 5-1). Each stride is made up of one *step* by each foot, and these two steps are normally symmetrical in length. The frequency of stepping is known as the *cadence* (steps/min). The speed of walking is calculated as the cadence times the step length. In practice, walking speed is often computed by recording the time needed to traverse a measured distance (e.g., 50-ft walking speed) (1).

The gait cycle is divided into segments (Fig. 5-1) that serve specific functions, each for a limited time during the gait cycle. Each lower limb supports the body during its *stance* phase and then leaves the floor for its *swing* phase, during which it advances (or steps). Although the swing phase is the “motion” portion of the gait cycle, one must remember that the horizontal push for the forward motion is the responsibility of the contralateral limb, which is in stance. This forward push requires adequate friction between the foot and the walking surface so that hip extension torques are translated into forward propulsion of the pelvis and swing limb.

## NORMAL HUMAN GAIT

The human gait pattern is normally fluid and shows continuous movement in the direction of travel. It has a natural repeating character, with the basic unit of the gait cycle, including one step with each foot. The basic function of walking involves each foot in turn either advancing forward as a step or supporting the body weight and balancing during the advancement of the contralateral lower limb. A period of double-limb stance (DLS) occurs between each step. During DLS, the

weight is transferred from one foot to the other in a complex coordinated pattern known as weight acceptance (or loading) and weight release (preswing) for each of the respective limbs (see Fig. 5-1). Although related, the associated actions of arising from sitting and starting and stopping walking will not be addressed in this chapter.

During each gait cycle, a carefully timed pattern of acceleration and deceleration is produced by the muscles. This muscle activity must overcome gravity, as represented by the vertical component of the ground reaction force (GRF), and provide forward propulsion (Figs. 5-2 and 5-3). The entire body is seen to be involved in the gait cycle, with movement occurring simultaneously in each of the three planes of movement, as well as each of the three axes of rotation. These six degrees of freedom of movement need to be considered throughout the gait cycle. For convenience in understanding, the gait cycle is divided into natural subunits called phases that have distinct functions in the gait cycle and have both propulsion and control aspects.

The stance phase of gait begins with the period of weight acceptance. Weight acceptance, also called loading, is a decelerating portion of the gait cycle where the foot must stop after traveling at about 4 m/s during the end of swing phase. This sudden stop requires controlled braking involving simultaneous action of the ankle, knee, and hip. (At the same time, the left leg is involved in the equally complex task of liftoff to initiate its swing phase.) The ankle is in a few degrees of dorsiflexion at heel strike and then rapidly plantar flexes under the control of an eccentric (lengthening) contraction of the anterior tibialis muscle, as well as the lesser dorsiflexors, until the foot is flat on the ground. Simultaneous with this, the knee begins to flex under the eccentric control of the quadriceps (the loading response), and the trunk reaches its lowest point during the cycle. The hip, which was flexed approximately 40 degrees at heel strike, immediately begins to extend on the pelvis as the trunk smoothly continues forward. The forward momentum of the trunk is similarly controlled by contraction of the hip extensors, both the gluteus maximus and the long hamstrings, resulting in controlled hip extension as the trunk moves forward. The hip and pelvis rotate opposite to one another at the same time, the hip rotation of the stance limb being internal. The critical role that the stance limb's hip extension and internal rotation has on forward propulsion was demonstrated by Sadeghi (2). He also reported that the ankle power is much less important to forward progression or propulsion.

**TABLE 5.1** Typical Temporal Gait Parameters for Comfortable Walking on Level Surfaces in Normal Adult Subjects

Temporal Gait Parameter	Average Value
Velocity (m/s)	1.33
Cadence (steps/min)	113
Stride length (m)	1.41
Stance (% gait cycle)	62
Swing (% gait cycle)	38
Double support (% gait cycle)	24

Modified from Perry J. *Gait Analysis: Normal and Pathological Function*. Thorofare, NJ: Slack; 1992, with permission.

As the left foot leaves the ground, the right hip continues to rotate internally as that limb enters the single-limb support portion of stance phase. The right ankle begins to passively dorsiflex as the tibia tilts forward and the pelvis lowers on the left in the familiar Trendelenburg tilt. The pelvis is also moving laterally to the right so that the center of mass (COM) of the body is aligned over the right foot to allow balance. During this period, the pelvis and COM of the body are rising. To achieve this, some of the kinetic energy of forward motion is converted into potential energy as the trunk rises against the force of gravity (3).

In the middle of single-limb stance (SLS) phase, the ankle reaches maximum dorsiflexion and the heel begins to rise from the floor. This heel rise signals a major shift in the right leg's function in the gait cycle as it ends its decelerating role and begins to serve as the acceleration for its step phase. The foot now rocks over to the forefoot as the knee extends, and the pelvis (not the hip) maximally rotates externally and the right hip maximally extends in preparation for opposite heel strike. The left lower limb is fully stretched out for its heel strike so that the pelvis is supported and the drop of the COM of the body is minimized.

The weight-release phase on the right must now shift weight support to the left lower limb while accelerating the

**FIGURE 5-2.** Quiet standing. The GRF, represented by the *solid line* with an *arrow*, is located anterior to the knee and ankle and posterior to the hip. The soleus muscle is active to stabilize the lower limb. (Courtesy of D. Casey Kerrigan, MD, with permission.)

right leg for its forward propulsion or swing phase. During weight release, the ankle is actively plantar flexed by concentric action of the gastrocnemius, soleus, posterior tibialis, and lesser plantar flexors. These forces contribute primarily to the

**FIGURE 5-1.** Periods of the gait cycle. The gait cycle is separated into two distinct periods of stance and swing. Functional tasks include weight acceptance and single-limb support during stance and limb advancement during swing. The stance period of the gait cycle includes initial contact, loading response, midstance, terminal stance, and preswing. The swing period includes initial swing, midswing, and terminal swing. (Reprinted from SLACK Incorporated: Perry J. *Gait Analysis: Normal and Pathological Function*. Thorofare, NJ: Slack; 1992, with permission.)

**FIGURE 5-3.** The eight phases of the gait cycle include initial contact, loading response, midstance, terminal stance, preswing, initial swing, midswing, and terminal swing. The GRF vector is represented by a solid line with an arrow. The active muscles are shown during each phase of the gait cycle. The uninvolved limb is shown as a dotted line. (Courtesy of D. Casey Kerrigan, MD, with permission.)

vertical components of the GRF. At the same time, right hip flexion is being produced by the iliacus, psoas, and tensor fascia lata muscles, and the left hip internal rotators are causing forward rotation of the right pelvis. These left hip muscles contribute much to the horizontal forces or forward propulsion of the right lower limb. As the toe finally leaves the ground as a result of this combined push and pull on the right lower limb, the swing phase is initiated, causing a step to occur.

During the beginning of swing phase, the right leg continues to accelerate as hip flexion, knee flexion, and ankle dorsiflexion combine to cause the toe to pass over the ground cleanly. Typically, the toe reaches a minimum height of less than 2.5 cm. at the middle of the swing phase. This minimal elevation is energy conserving by reducing the work done to elevate body parts against gravity. This closeness to the ground can be a safety problem, causing stumbles on uneven ground, but the gains of energy efficiency caused by reducing the step height are important enough for this safety risk. The energy-conserving nature of the gait cycle, in part attributable to these mechanics and its highly repetitive and symmetrical nature, will be discussed in more detail, but most of us have experienced the rapid fatigue caused by high stepping (“steppage gait”) when traversing deep snow or the lack of repetitive steps when walking on very uneven ground.

The second half of the swing phase returns the right leg into a role of decelerating as the forward motion is slowed in preparation for heel strike. The ankle is held in dorsiflexion while the hip flexes and the knee extends. This combination, along with the forward rotation of the right pelvis and external rotation of the right hip, results in maximal length of the step.

Any injury or dysfunction of a joint or muscle-tendon unit that reduces the step length will have a major impact on the efficiency of walking. At the end of swing, the hip extensors serve to brake the forward flexion of the hip; and, at faster gait speeds, the hamstrings slow and control the knee extension. The speed of the leg and foot must be controlled to prevent slipping at heel strike.

## ENERGY CONSERVATION AND GAIT

Energy is consumed in three different categories during walking (4). First, there is the work of moving the body’s mass through the required distance in a period of time. Second, there is the work done to accomplish the up-and-down motion of the trunk for each step as the pelvis rises to a position above a single supporting leg during midstance and is lowered during double support when it lies between the two lower limbs supporting it at opposite angles. Third, energy is being consumed by the body for general, or basal, metabolism. Because work requires energy and faster walking involves more work, there is an energy cost. However, since the constant basal metabolic rate continues, as well as some muscular energy consumption for standing, the total energy consumed per unit distance traveled is seen to decrease initially as speed increases from a very slow walking speed. As an optimal speed is reached that is traditionally called comfortable walking, the combined metabolic rate is most efficient for traveling over the ground. The higher energy requirements of faster walking and running require greater work output by the muscles.

**FIGURE 5-4.** Hypothetical compass gait. The pelvis is represented by a single bar with a small cuboid representing the body's COM. The legs are rigid bars articulating only at the hip. No foot, ankle, or knee joints are present. The pathway of the COM is a series of interconnecting arcs. (Reprinted from Saunders JB, Inman VT, Eberhart HD. The major determinants in normal and pathologic gait. *J Bone Joint Surg.* 1953;35A:543–558, with permission.)

The vertical displacement of the body is minimized by a number of factors that are known as the *determinants of gait* (5). These six determinants operate independently but simultaneously to produce a smooth sinusoidal vertical and horizontal path, which has one vertical peak and trough for each step. There is also one lateral sinusoid, or curve, for each stride as the body moves toward the supporting foot during each cycle. To illustrate the effects of the determinants of gait,

they are removed and replaced in models of the gait cycle as shown in Figures 5-4 to 5-8. This “compass gait” analysis was restudied by Della Croce et al. (6) with the inclusion of data recorded in a contemporary gait lab, largely reaffirming the model.

The first determinant of gait is the rotation of the pelvis (Figs. 5-4 and 5-5). During each step, the pelvis rotates forward on the side of the swinging limb. The axis of this rotation

**FIGURE 5-5.** Effect of pelvic rotation in the transverse plane. The slight rotation of the pelvis in the transverse plane during double-limb support reduces the elevation needed by the COM when passing over the weight-bearing leg during midstance. (Reprinted from Saunders JB, Inman VT, Eberhart HD. The major determinants in normal and pathologic gait. *J Bone Joint Surg.* 1953;35A:543–558, with permission.)

**FIGURE 5-6.** Pelvic obliquity during single-limb support. A drop in the pelvis on the non-weight-bearing side allows for a reduction in the peak height of the COM during midstance. (Reprinted from Saunders JB, Inman VT, Eberhart HD. The major determinants in normal and pathologic gait. *J Bone Joint Surg.* 1953;35A:543–558, with permission.)

is the hip joint of the stance leg, which undergoes internal rotation. As the pelvis forms a bridge between the two hips, it reduces the angle of intersection of the thighs to reduce the vertical descent of the trunk.

The pelvic Trendelenburg motion, or pelvic list, is the second determinant (Fig. 5-6). The pelvis drops a few degrees so that the hip of the leg in swing phase is lower than the hip of the stance limb. This reduces the vertical rise of the COM of the trunk and reduces the work of lifting this mass. The cost of this pelvic list is to reduce the space for toe clearance, but this is an affordable cost. Pelvic list, as well as rotation, has been shown to decrease at slower speeds (7). This fact, and the data that reveal that these motions are less important modifiers of the vertical movement of the COM (6), suggests that these movements are important to the control of the momentum during forward propulsion.

Knee flexion in stance phase is an important determinant of gait for two reasons. First, it provides a shock-absorbing mechanism at the beginning of the stance phase. The reduction of the shock of foot impact on the floor helps to maintain momentum and thereby reduces energy loss of stopping and restarting the gait cycle. Also, the knee flexion in stance reduces the height of the hip joint in midstance. This additional height reduction prevents energy loss from lifting the body but at the cost of quadriceps muscle work.

Lateral displacement of the pelvis also occurs during each step (Fig. 5-7). The pelvis and trunk must move to the stance side to balance the COM of the trunk above the stance foot. This also aligns the tibia into the vertical position during stance. This determinant of gait is a net loss of energy since it causes upward movement of the body, but it is necessary for balance in bipedal gait.

The trunk and shoulder rotate during normal gait in a direction opposite to the pelvic rotation. This 180-degree phase shift of total trunk movement balances the angular acceleration so that balance and forward momentum are maintained. Smooth, coordinated movement here is an energy advantage.

The obliquity of the subtalar joint provides a unique relationship between the motion of the foot and that of the shank. Dorsiflexion of the foot causes lateral movement of the forefoot and vice versa. During stance, the passive dorsiflexion of the ankle, therefore, causes internal rotation of the tibia to partially match that similar movement in the hip. This combined rotation is then reversed during the end of stance or weight release.

Sagittal plane foot and ankle movement is referred to as the three “rockers.” The three components are at heel strike, during foot flat, and during toe-off. Each of these has work- and energy-saving factors (Fig. 5-8). For the first rocker, the dorsiflexion of the foot causes the heel to stick out and produce a net lengthening of leg length to maximize the length of the step. This extra length is quickly lost during weight acceptance, when it is no longer needed. Also during this time, the resisting ankle dorsiflexion muscles provide a shock-absorbing descent of the forefoot. During the second rocker, dorsiflexion of the foot occurs during midstance. This serves to reduce the length of the leg until the pelvis passes in front of the ankle. As the heel rises after midstance, the third rocker occurs. The elevation of the heel increases the leg length during push-off and so limits the amount of drop that is experienced by the pelvis. The rockers of the heel, midfoot and forefoot are therefore useful in minimizing the vertical work of the body movement. The second utility of the rockers

**FIGURE 5-7.** Effect of narrowing the walking base. A shift in the position of the body over the stance limb, combined with the natural valgus between the femur and the tibia, allows for a reduction in the lateral displacement of the pelvis. Reduction in the width of the gait cycle reduces the displacement of the COM. (Reprinted from Saunders JB, Inman VT, Eberhart HD. The major determinants in normal and pathologic gait. *J Bone Joint Surg.* 1953;35A:543–558, with permission.)

is to provide a rolling-like mechanism of foot during stance so that momentum is preserved. Della Croce's work suggests that heel rise and forefoot support may be the most important determinant of gait (6).

**FIGURE 5-8.** Sinusoidal pathway of the COM. The combined interaction of the knee, ankle, and foot allows for the reduction and smoothing out of the displacement of the COM. ## KINETICS

A complete understanding of gait requires knowledge of the kinetics of movement in addition to the kinematics of motion discussed in the preceding sections. Kinetics is the science of forces acting on bodies to cause motion. Gait kinetics explains the causes of the motions of gait.

The basic principles of kinetics are Newton's three laws of motion. The first is that a body (of mass  $m$ ) will change velocity (accelerate ( $a$ ) or decelerate) only if a force is applied to it. Also, this change in velocity ( $v$ ) is proportional to the force ( $F = ma$  and  $a = \Delta v$ ). Newton's third law, the law of action and reaction, is very important for the study of gait and other aspects of biomechanics. This law relates the forces interacting between the foot and the floor as always being equal and opposite. One can therefore measure the forces of ground reaction on the foot with a force plate and begin to understand the net forces acting on the lower limb and on the body as a whole (Fig. 5-9).

The GRF is represented by three directions perpendicular to each other: horizontal (fore/aft), side to side, and vertical. One can also measure the twisting or rotational load on the force plate as the rotating limb is constrained from moving by friction. The force plate also allows the direct calculation of the center of pressure on the foot. During stance phase, the center of pressure starts at the medial heel. As foot flat occurs and the limb progresses to single stance, the center of pressure typically moves laterally as it progresses forward. Then, after heel rise and into weight release, the center is in the forefoot, progressing to the medial side again.

From the center of pressure, the net vector of the three GRFs can be located at each instant during gait (see Fig. 5-3). This force vector (i.e., a force that has magnitude and direction) acts on each of the limb segments as well as each joint. The perpendicular distance between the GRF and each joint defines a moment arm, or leverage, that when multiplied by the force creates a moment of rotation, or torque, about the joint's axis.

Through the process known as inverse dynamics, these forces can be calculated sequentially from the ground and foot up to the trunk. Changes in vertical position of the trunk COM result in changes in the potential energy, and forces

**FIGURE 5-9.** Ground reaction loads (forces and vertical torque) during stance of one foot for an adult woman walking at 1.18 m/s. Key events are marked: *B, E*—vertical forces exceed body weight at weight acceptance and release (force means acceleration is occurring); *G, H*—posterior shear forces decelerate during loading and reverse to accelerate for push-off; *J, K*—the ground reaction torque is in response to rotations of the limb. (Reprinted from Davis RB, Kaufman KR. Kinetics of normal walking. In: Rose J, Gamble JG, eds. *Human Walking*. 3rd ed. Baltimore, MD: Lippincott Williams & Wilkins; 2005, with permission.)

causing changes in velocity of limb segments will affect the kinetic energy. Only small amounts of energy change are seen in the transverse and frontal planes, and so studies of gait usually focus on only the energy changes in the sagittal plane relating to forward progression and vertical support.

Power is defined as work per unit time. The net power of each joint is shown in Figure 5-10. Keep in mind that this net power is not the same as the individual muscle power or the metabolic power representing those changes in energy levels. It is only the balanced result of those interactions with the GRF. This net power at each joint can represent generation of energy (+) or absorption of energy (-). For example, study the knee power in Figure 5-10. The power is initially negative (decelerating) as the extensor torque produced by the quadriceps is overcome by the flexion moment of the ground reaction. As the trunk progresses forward, the GRF vector angles forward and reduces the flexion moment as the knee stabilizes. Later, the extensor muscles and GRF produce extension together and the net power is positive (accelerating).

## ELECTROMYOGRAPHY IN GAIT ANALYSIS

Actively contracting muscles under neural control produce electromyographic (EMG) activity. This EMG signal is easily

recorded and amplified so that the muscle activity can be correlated with the kinematics and kinetics of gait. In carefully controlled experiments of isometric contraction, a linear relationship exists between the EMG signal and the muscle force. However, this relationship is greatly disrupted by the movement of the muscles during gait, so EMG does not give accurate information about muscle forces (8). For example, EMG analysis of the rectus femoris' role as a hip flexor in early swing phase demonstrates that higher amplitude EMG signals are produced at faster walking speeds (9). The muscle must exert greater force to flex the hip more rapidly, but the relationship is nonlinear and complex, and one is still unable to make quantitative conclusions about muscle force from EMG signals alone.

Multichannel amplifiers are used in gait laboratories to record from several muscles simultaneous to the recording of kinematic motion (Fig. 5-11). The electrodes used for this recording may be either surface electrodes or flexible intramuscular (IM) wire electrodes (8). Surface electrodes are noninvasive and record a larger volume of the target muscle. They are unable to record signals from deep muscles and may record unwanted signals from muscles that are adjacent to the target muscle. Wire electrodes can be located to record more precisely from any muscle, including those that are deep. However, in addition to being more painful, the wire electrodes may dislodge or break during activity. EMG also allows the measurement of muscle fatigue during sustained activity. As lactic acid accumulates in a muscle with exercise, the membrane propagation of the action potential (AP) is slowed. This slowing of velocity is seen as a reduction in the frequency of the recorded EMG signals (8).

## DEVELOPMENT OF GAIT

Normal adults perform the task of walking without significant active thought or effort. It is a process that is learned and eventually mastered in childhood. Understanding the development of gait is critical to any physician performing neuromuscular examinations of children. To appreciate subtle normal variations or pathologic findings, a physician must have a thorough knowledge of normal development, understand its relationship to gait, and use a systematic approach (10).

### Early Infant Development

The first few years of life are characterized by the most rapid growth in the human life span (11). During this period of maturation of the central and peripheral nervous systems, the development of gait emerges according to a typical pattern of motor development: rostral to caudal, proximal to distal, and mass movement to specific action (11,12). Although there is variation in the development of each child, some general statements concerning milestones of development are appropriate. Head control is a prerequisite to ambulation that begins to improve by the age of 2 months (12,13). Further improvement in head control is seen at the age of 3 months, along with an integration of primitive reflexes

**FIGURE 5-10.** Kinetics and kinematics at the hip, knee, and ankle. Sagittal joint motion, moments, and power are shown. (Courtesy of D. Casey Kerrigan, MD, with permission.)

**FIGURE 5-11.** General muscle group activity as a percentage of the gait cycle in normals. (Courtesy of D. Casey Kerrigan, MD, with permission.)

with occasional bobbing during supported sitting (11). From the ages of 4 to 6 months, children learn prone propping followed by rolling. Rolling is first achieved from prone to supine, followed by supine to prone, and by this time, independent sitting is usually achieved with arm support. By 9 months, a significant increase in mobility ensues with the advent of belly crawling and standing up by pushing onto hands and knees (11).

Achievements of these skills as well as sitting, creeping, and pulling to a stand are prerequisites that a child must master before supported and independent walking. Balance and support, two major skills required for independent walking (14), are practiced as a child progresses toward supported walking.

### Supported Walking

Around 8 to 10 months of age, children begin to walk by holding onto objects. For example, a child may grab a crib surface or table while attempting to maneuver across a room. On the average, supported walking or cruising lasts 2 months, with significant variability (15). This stage is characterized by the use of arms for support and is a transitional phase that precedes independent walking. In comparison to independent walking, supported walking is characterized by a longer gait cycle time, longer stance phase, increased variability in successive strides, and decreased walking speed. The average walking speed in supported walking is noted to be 39 cm/s, with stride length of 44 cm and 65% of gait cycle being spent in the stance phase (16).

When compared with normal adults, children reveal greater angles of hip flexion during walking. The hip extension pattern shows increased variability, poor smoothness, and decreased total amplitude. There are also striking differences in knee and ankle patterns between normal adults and children during supported walking (16). Knee pattern and amplitude of flexion differences are most impressive during the stance phase. At initial floor contact, Statham and Murray (16) found average knee flexion of children in supported walking (stance) to be 21 degrees, which is in sharp contrast to that of adults where knee flexion was 1 degree. Knee flexion angles during swing were similar to that of adults.

In supported walking, there is no clear heel strike, as a child may make initial floor contact with the heel, flat foot, or forefoot (i.e., toe walking) (16–18). This is in contrast to normal adults, where heel strike is very consistent and is followed by ankle plantar flexion rather than ankle dorsiflexion. The lack of full knee extension and ankle dorsiflexion at the end-of-swing phase have been cited as possible causes for variability at foot strike (15). Initial floor contact is followed by ankle dorsiflexion (modified loading response) in supported walking regardless of which part of the foot makes initial contact. The maximums of ankle dorsiflexion and plantar flexion angles, the degree of ankle dorsiflexion at initial floor contact, and the maximum ankle dorsiflexion during swing phase are also greater in supported walking than they are in adults (16).

In summary, prominent features of supported walking in children that are in contrast to those of adults include increased hip flexion, decreased knee extension, increased ankle

dorsiflexion, decreased walking speed, increased variability, and decreased smoothness.

### Independent Walking

Following supported walking, children progress to independent walking with a premature gait pattern and, during this phase, are referred to as “toddlers” (15). This is a transitional period between supported walking and a mature gait pattern. Collection of data using quantitative gait analysis in this age group often proves to be very difficult, as these children do not follow simple instructions and display significant variability from one gait cycle to the next. Inconsistent gait pattern, wide-based support, increased hip flexion, and lack of reciprocal arm swing are some of the hallmarks of gait in toddlers. In general, the development of walking skills is completed by the age of 5 years (19,20).

In the progression from supported walking to independent walking, there is a trend toward decreasing excessive hip flexion and greater extension at initial floor contact; however, these movements are still not identical to those of adults (16). On initial floor contact, the knee in independent walkers is held in less flexion, and there is the emergence of an adultlike knee flexion during loading. This knee flexion is established in most children by the age of 2 years (21). Consistent initial floor contact with the heel is observed by 22.5 weeks after initiating walking and at the average age of 18.5 months. A variable amount of toe walking continues during this age range. Subsequent to this, there is the development of a mature foot and knee mechanism during stance phase, which develops about 27 weeks after the initiation of independent walking, at a mean age of 19.5 months (17). There is a significant decrease in the excess ankle dorsiflexion movement at initial floor contact, compared with that seen in supported walking. In mature adult gait, the swing phase is marked by hip and knee flexion initially, followed by continued hip flexion and knee extension during mid and terminal swing, whereas the ankle begins dorsiflexion during midswing. These same swing phase motions are present in most toddlers, with slight modifications until the normal adult motions are achieved, typically by the age of 3 years (15).

Sutherland et al. (19,21) proposed five important determinants of mature gait: duration of SLS, walking velocity, cadence, step length, and the ratio of pelvic span to ankle spread. The gait of a toddler demonstrates significant changes in each of these determinants as he or she approaches gait maturity. The duration of SLS increases steadily from 32% of the gait cycle at 1 year to 38% at age 7 (19,21). The most rapid changes were observed in children before 2½ years of age.

Walking speed increases as a child progresses from supported to independent walking; however, children are inconsistent in their ability to manage their walking speed (20). Average speed in independent walkers is found to be 64 cm/s, in contrast to 39 cm/s for supported walkers (16). Furthermore, increased cadence seems to be the main reason for the noticeable increase in walking velocity in the toddler. Sutherland (21) reported that walking velocity increases with age in a linear manner from 1 to 3 years, at a rate of 11 cm/s/y, and from 4 to 7 years, the rate of change diminishes to 4.5 cm/s/y with a continued

linear relationship. As independent walking matures, there is a decrease in cadence with an increase in stride length with a net result of faster walking speed (15,21). The primary reduction in cadence occurs between the ages of 1 and 2 years, with a gradual decrease thereafter. The cadence at 7 years is noted to be 26% greater than in a normal adult (21). As one would expect, the stride length increases with height, and this leads to faster walking for taller children (and adults). Todd has developed a mathematical equation that defines this nonlinear relationship for children during development without regard to age (22).

Sutherland et al. (19,21) defined the ratio of pelvic span to ankle spread, their fifth determinant of mature gait, as the ratio of body width at the anterior superior iliac spine and distance between ankle centers during double support. They found that the ratio increased in a linear fashion from ages 1 to 3 years and then remained constant. Burnett and Johnson (17) found that foot placement moves within the lateral dimensions of the trunk by 17.5 weeks after initiating independent walking and continues to narrow for several more weeks. Reciprocal arm swing, another feature seen in mature gait, is universally seen in children by the age of 4 years and rarely before the first birthday (21). Burnett and Johnson (17) reported the development of reciprocating arm swing by 22 weeks after initiating independent walking.

The trend of muscle timing during the toddler years is to shorten the duration of muscle action during the gait cycle and establish normal phasing by reducing unnecessary muscle activity (15). Because of convenience as well as other obvious issues, EMG data in toddlers have been collected primarily from surface electrodes rather than from IM wires. Quadriceps and hamstring activities are prolonged in a toddler but approach normal timing by 2 years (21). No change was seen in the gluteus medius EMG activity with increasing age; however, there was shortening of the time that the gluteus maximus was active during stance phase. Medial and lateral hamstring activities were primarily prolonged, during stance phase, in the immature gait of 12- to 18-month children, with mature patterns emerging around the age of 2 years. Similar findings were also observed for the tibialis anterior and gastrocnemius-soleus muscle complex when referring to the late swing phase and premature stance phase activities seen in these muscles (21).

Normal gait development is a complex process. Pathologic gait is even more complex, and walking is considered to be a sensitive measure of neuromuscular development (23). By understanding gait development and utilizing both careful observation and experience, the physiatrist can detect pathologic gait in this changing background. An understanding of normal gait development, including age-related changes, is crucial for any physician performing a pediatric neuromuscular examination.

## ABNORMAL GAIT

Several examples of abnormal gait have been selected to help reinforce important basic biomechanical concepts of human motion. When presented with a patient who has an abnormal

gait pattern, it must be determined whether the abnormal movement patterns have (a) potentially detrimental functional consequences, such as increased fall risk, excessive energy expenditure, or adverse joint stresses that may predispose to degenerative changes; (b) only cosmetic significance; or (c) advantages in adapting and are functionally beneficial. Often deciding that a gait pattern is abnormal is apparent from the patient's history and observational gait analysis. Quantitative kinematic and kinetic data from gait analysis are used to differentiate the primary gait deviations from those that are secondary (or compensatory) (24,25).

The general appraisal of a patient with an abnormal gait involves assessing the symmetry and smoothness of movements, including trunk movement, arm swing, stride length, width of gait base, balance, and degree of effort. Useful additional information will result from having the patient increase and decrease his or her gait speed, observing differences with and without use of any hand-held gait aid or orthosis (if going without such devices is feasible), and if available, observing the patient walking up an incline and down a declined surface. Then, a more systematic and methodical evaluation should be performed, focusing on specific segments and joints, from head to toe or vice versa. A patient's gait should be observed from the front, back, and both sides, and the examiner should note the portion of the gait cycle during which a particular deviation occurs.

When interventions are planned to improve a patient's gait, specific goals need to be determined from the outset, including the patient's ultimate ambulatory goal (full community, limited community, or household level ambulation). When muscular weakness is a contributor to an abnormal gait, strengthening exercises for the agonist and stabilizing muscles may be appropriate. However, with a progressive disease process, or following the destruction of most motor units of a particular muscle group, compensating for the weakness with appropriate orthoses and hand-held gait aids should be considered along with a manual wheelchair or powered mobility device. If spasticity is present, spasticity-reducing interventions include physical therapy; oral, injectable, and intrathecal pharmacologic agents; and tendon surgery. It is important to remember that spasticity may actually have limb-stabilizing effects that can be beneficial from a functional perspective (26). For patients who wear a lower limb prosthesis or brace, gait abnormalities with a prosthetic or orthotic cause should be addressed through adjusting or replacing prosthetic or orthotic components, whereas patient-related causes may require training the person in optimal prosthetic or orthotic ambulation, skin care, muscle stretching and strengthening, balancing, and endurance and aerobic exercises.

## Transfemoral (Above-Knee) Amputation

The first example will consider a patient who has undergone a transfemoral (TF) amputation. More detailed discussions of TF amputee gait patterns are available elsewhere (27–31), and Chapter 74 provides information about potential gait deviations in the TF amputee. For the purposes of this example, we will assume a midthigh level of amputation, no significant hip

flexion contracture, use of an ischial containment socket, and optimal prosthetic suspension. The shorter the residual limb is, the shorter the lever available to control the prosthesis, resulting in the hip abductors on the prosthetic side becoming less effective in stabilizing the pelvis (32). The ischial containment or narrow medial-lateral socket is usually preferred to the older quadrilateral socket design, because of advantages in both comfort and biomechanics (33). Finally, suboptimal suspension results in a functionally long prosthetic limb, with resultant difficulty clearing the foot during midswing phase unless compensatory motions (e.g., hip hiking or an abducted gait on the prosthetic side, or vaulting on the intact side) are performed.

Prosthetic knee stability is of paramount importance to the TF amputee, whose remaining quadriceps can no longer serve the function of controlling knee flexion during loading. During the initial, weight acceptance portion of stance phase, the prosthetic knee unit will be more stable when the GRF line passes *anterior* to the knee. For a TF amputee with a longer, stable residual limb and normal strength, the prosthetist may elect to place the axis of rotation of the knee unit *anterior* to the trochanter-knee-ankle (TKA) line—the line drawn during static alignment that passes through the greater trochanter, knee, and ankle joint centers in the sagittal plane—to provide “voluntary control” over prosthetic knee stability (32). Although this situation requires greater voluntary activation of the hip extensors beginning at the moment of heel strike, which via closed-chain kinetics effects an extension moment at the knee, the advantage is easier knee flexion during terminal stance and preswing, since the GRF line is more readily positioned *posterior* to the knee joint axis (29,30). On the other hand, for a TF amputee with a weakened residual limb, the prosthetic knee joint axis would be placed *posterior* to the TKA line to afford greater knee stability but with the disadvantage of greater difficulty achieving knee flexion during late stance. Current prosthetic technology provides greater knee stability during early stance and more readily achieved knee flexion during late stance with mechanical polycentric knees, simple fluid or pneumatic-controlled knees, and the increasingly popular microprocessor-controlled knee units (34).

With regard to the prosthetic foot and ankle, the more rapidly the prosthetic foot advances from heel strike to foot flat, the more rapidly the GRF line progresses to a position anterior to the knee joint axis, with a resultant extension moment at the knee. Any restriction in ankle plantar flexion, such as may result from an excessively stiff plantar flexion bumper in a single-axis prosthetic foot, would serve to destabilize the prosthetic knee during early stance. Given that there is an ankle dorsiflexion moment from midstance to terminal stance, unchecked dorsiflexion, such as can result from a worn dorsiflexion bumper in a single-axis prosthetic foot, would predispose to late-stance phase buckling of the prosthetic knee because of unrestricted forward motion of the prosthetic shank (32).

### Foot Drop Gait

A “foot drop” condition results from weakness of the anterior compartment (dorsiflexor) muscles of the leg, ankle plantar flexor spasticity, or an ankle plantar flexion contracture. With

the exception of the last condition, an ankle-foot orthosis (AFO) is typically used to compensate for foot drop (35). Without an AFO, foot drop results in gait deviations, resulting in increased energy expenditure from such compensatory motions as hip hiking or excessive hip and knee flexion (i.e., steppage gait) to achieve foot clearance during swing phase. Foot slap may occur immediately following heel strike in mild weakness, or, if severe, the forefoot makes initial contact in stance phase (36). Spastic plantar flexors usually necessitate a rigid, solid (nonarticulated, to reduce activation of the plantar flexors’ stretch reflex) AFO designed to maintain a 90-degree (neutral) position of ankle dorsiflexion (if achievable). In the absence of significant spasticity, however, spring-assisted dorsiflexion is often used. This type of component can be incorporated into both plastic and double metal upright AFO designs and allows partial ankle motion—from neutral to up to full ankle dorsiflexion—with less adverse effect during stance phase compared with a solid plastic AFO or fixed-ankle metal AFO. Either an AFO with assisted dorsiflexion or an AFO that allows no ankle motion will usually prevent ankle plantar flexion beyond neutral (via a 90-degree “plantar flexion stop”), resulting in little difference between the two from initial contact through loading response. The inability of the ankle in an AFO to plantar flex beyond neutral keeps the GRF line posterior to the knee, resulting in a knee flexion moment from initial contact through midstance. However, from midstance to terminal stance, a solid AFO does not allow the tibia to move progressively forward via dorsiflexion, which interferes with the second of the “three rockers” described earlier, and instead necessitates early heel rise from knee flexion. Neither AFO design allows ankle plantar flexion to occur as would normally take place from terminal stance through preswing. Maintaining foot clearance in a narrow range is critical during initial and midswing phases, and both of these AFO designs prevent toe drag by restricting plantar flexion.

### Weak Calf Gait

In contrast to ankle dorsiflexor weakness, which affects the entire swing phase and the first half of stance phase, weakness of the ankle plantar flexors results in deviations involving the second half of stance phase. In normal gait, the ankle plantar flexors contract eccentrically to control the rate at which the tibia advances forward over the supporting foot. Weakness of this muscle group, as may result from such conditions as Achilles tendon injury, tibial nerve injury, S1 radiculopathy, or lower lumbar myelomeningocele, results in excessive and untimely forward progression of the tibia during the midstance to late-stance phase (2). This excessive passive ankle dorsiflexion during terminal stance prevents normal heel rise, which functionally shortens the stance limb and reduces the effect of the toe (or third) rocker. This leads to premature contralateral initial foot contact that decreases stride length (36). It is shortened step, not deficient “push-off,” that impairs forward progression in the presence of calf weakness (2). The failure of vertical support from the calf also causes ipsilateral

pelvic drop, which lowers the body COM (6). The excessive drop in the body COM results in marked energy loss, since the pelvis must rise again to a normal height during the stance phase of the sound limb.

### Gluteus Medius Gait

The gluteus medius is the primary hip abductor; the gluteus minimus and tensor fascia lata are secondary hip abductors; and all three share the same spinal root and peripheral nerve supplies. With open-chain kinetics (when the foot is unrestrained), activation of the hip abductors results in hip abduction. However, with “closed-chain” kinetics (when the foot is in contact with a surface such as the floor), activation of the hip abductors does not result in lower limb movement, because of friction between the foot and the supporting surface. Rather, the angle between the femur and the pelvis is increased by pelvic tilting (assuming the pelvis is unrestrained). During normal gait, the hip abductors—chiefly the gluteus medius—are active during SLS to limit the degree to which the contralateral pelvis lists (or dips) downward. Normally, this is limited to 5 degrees of pelvic list (Inman’s second major determinant of gait) (37). Excessive pelvic tilt, or instability of the pelvis in the coronal plane due to hip abductor weakness, may present as difficulty with foot clearance during midswing phase on the opposite side. A gluteus medius type gait may be due to hip abductor weakness, hip joint pain, or both. The excessive energy demands of an uncompensated gluteus medius gait—characterized by excessive pelvic list, lateral protrusion of the pelvis on the affected side during stance phase, and an obligatory step-page gait on the contralateral side—are somewhat lessened by a compensated gluteus medius gait in which the person employs excessive trunk leaning over the affected limb with an associated medial pelvic deviation during stance phase (36). This effectively reduces the large hip adductor moment that results from unloading the contralateral limb and that is normally controlled by fully functioning hip abductors. A lesser demand for a forceful contraction of the hip abductors results in a lesser axial, or compressive, load on the hip joint surfaces. In addition to ipsilateral trunk lean during stance phase, further reduction in hip joint loading may be achieved through the use of a cane in the opposite hand. Finally, the gluteus medius gait, in contrast to most other gait deviations, becomes *less* evident with *faster* walking, since the shorter duration of stance phase means that there is a shorter time period over which the weakened hip abductors must act to try to stabilize the pelvis.

### Spastic Gait

#### Poststroke

Gait deviations following stroke may manifest in a variety of ways, depending on the severity, location, and extent of damaged brain tissue; the amount of time that has passed since the stroke; and the rehabilitative interventions that have been implemented. For purposes of illustration, this discussion will relate to typical gait abnormalities that may follow the common middle cerebral artery distribution stroke, with resultant

unilateral weakness and spasticity. Typical abnormal movement patterns include reduced knee flexion during swing and stance phases (spastic paretic stiff-legged gait), knee hyperextension (dynamic recurvatum) during stance, and excessive ankle plantar flexion (equinus) during swing and/or stance (38). Each of these has the potential detrimental effect of raising the energy requirement for walking.

Reduced knee flexion during swing phase may necessitate such compensatory maneuvers as hip circumduction, hip hiking, and contralateral vaulting with excessive elevation of the pelvis to avoid toe drag. Insufficient knee flexion during stance results in a relatively elevated position of the body’s COM. Dynamic knee recurvatum may predispose the knee to injury from overstretch of ligament and posterior capsular structures as the (external) GRF and the (internal) muscle force combine to create a knee extension moment (39).

Ankle equinus during swing phase may be due to ankle dorsiflexor weakness, plantar-flexor spasticity, or ankle plantar flexion contracture. During stance phase, the latter two causes may contribute to the development of dynamic knee recurvatum by preventing the progressive ankle dorsiflexion that normally begins during loading response and continues through terminal stance (36). All three causes of ankle equinus, depending on severity, may necessitate one or more of the compensatory motions during the swing phase (mentioned above) that can reduce toe drag.

Another feature of gait following stroke is reduced speed, with marked asymmetry of stepping (40). Many authors have reported a reduced percentage of the gait cycle in single-limb stance (SLS) on the affected side (40,41). However, the most striking deviation from normal gait is the prolonged period of weight release for the hemiparetic limb during DLS (38). Poor weight release is associated with both a low angular velocity of hip flexion and a delay in initiating flexion, which is seen as a long period of double-limb stance. We also observed that SLS on the affected side is the same as SLS in normal gait when measured in absolute time (Fig. 5-12) (38). SLS lasts just long enough to allow advancement of the sound limb, which is a relatively fixed period of 0.34 to 0.38 seconds. As gait slows, this fixed time may become a very small portion of the gait cycle time. The poor angular velocity of the weak hip contributes to poor knee flexion during swing, which is passive at normal gait speed. This compounds any knee extensor muscle contraction caused by spasticity (38,42).

### Diplegic Cerebral Palsy

Of the various types of cerebral palsy (CP), the spastic form is the most prevalent. Sutherland and Davids classified the gait abnormalities at the knee in patients with CP into four types: jump, crouch, recurvatum, and stiff (43). Some of the features of a spastic gait with knee recurvatum, or a “stiff-legged” knee gait, have been discussed under post-stroke gait. In jump gait, excessive knee flexion is present during early stance phase but with normal or near-normal knee extension during the midstance and late-stance phases. Crouch gait typifies the spastic diplegic form of CP and is

**FIGURE 5-12.** Mean duration (absolute time) of the phases of the gait cycle for each performance level in adult hemiplegic walking. The percentage of the gait cycle that each phase represents is printed below each bar. The four bars represent three different functional levels of hemiplegia after stroke in comparison to normal gait. The bars are arranged to allow comparison of the duration of the SLS phase for the hemiplegic side. *HFS*—foot strike on the hemiplegic side; *OTO*—toe-off on the contralateral (unaffected) side; *OFS*—foot strike on the contralateral side; *HTO*—toe-off on the hemiplegic side. (Reprinted from de Quervain IA, Simon SR, Luergans S, et al. Gait pattern in the early recovery period after stroke. *J Bone Joint Surg.* 1996;78A:1506–1514, with permission.)

characterized by excessive knee flexion throughout the stance phase and variable knee alignment during the swing phase (44). In addition, the hips are often adducted and internally rotated (scissor gait), and there may be equinus and forefoot abduction (44). Although one might assume that the spasticity evident on static examination is the main culprit responsible for the abnormal movement patterns, gait analysis has revealed abnormal dynamic muscle activation patterns, including excessive co-contraction of agonists and antagonists, with resultant increased joint stiffness and weakening of agonist force production as playing a more central role (45). Hamstring spasticity has been proposed as being primarily responsible for the crouch position, but gait analysis has additionally identified hip or knee flexion contractures, ankle plantar flexion contractures, and ankle plantar-flexor weakness as being contributory (36,44,45).

### Changes in Spastic Gaits Following Spasticity-Reducing Interventions

The mere presence of spasticity does not necessitate the initiation of spasticity-reducing interventions to improve a spastic gait pattern. As noted for CP, disordered muscle activation patterns may be partially or primarily responsible for abnormal movement patterns. And as noted for gait following stroke, delay in the initiation and speed of hip flexion during the initial swing phase, rather than quadriceps spasticity, may be responsible for reduced knee flexion during swing phase. Even if quadriceps muscle spasticity is responsible for stiff-legged gait, only one or

two heads of the quadriceps may be involved. Although intense and prolonged activity in the rectus femoris at the junction of preswing and initial swing phases is often identified, similar abnormal firing of the vastus intermedius, with or without co-contraction of hamstring muscles, may also be occurring. Differentiating these muscle contraction patterns necessitates dynamic, multichannel EMG recording during quantitative gait analysis (36,46).

Surgical procedures such as rectus femoris release have been used to eliminate the detrimental effect of abnormal rectus femoris activity, with resultant enhanced initial swing phase knee flexion in CP patients and hemiplegic stroke patients (47–53). Motor nerve block of the rectus femoris has been shown to improve maximal swing phase knee flexion, the slope of the knee motion curve at toe-off, and gait speed in patients with spastic stiff-legged gait who also had sufficient hip flexor strength and no abnormal EMG activity of the vastus muscles during the initial swing phase (54). Alcohol neurolysis of the sciatic nerve to reduce hamstring spasticity in hemiplegic stroke patients has produced beneficial effects lasting 6 months (55). Selective dorsal rhizotomy in CP patients has been shown to normalize co-contraction during knee extension but was without benefit to co-contraction during ankle plantar flexion the majority of the time (56).

Electrical stimulation of nerves and muscles has a long history in attempts to improve the functional walking in persons with upper motor neuron injury and spastic paralysis (57–59). Liberson envisioned an electrical replacement for the ankle-foot

orthoses (59). Later work expanded this concept into complex systems that use multiple site of stimulation with implanted wires to produce more complex movements (60,61). Some of these devices functioned with added stabilizing support of mechanical orthotics, and many were successful in the laboratory setting (60,61). Further development of this technology has redirected attention on Liberson's concept of a device that is simple and safe enough for home use as an exercise and training device (62,63). In persons with hemiplegia after stroke and incomplete spinal cord injury (SCI), these electrical stimulators activate the fibular nerve during swing phase to produce walking patterns that are faster, farther and more efficient, and with improved toe clearance (60,61,63). The improved toe clearance comes with the finding that fibular nerve stimulation improves knee flexion as well as ankle dorsiflexion (57,60). In addition, the evidence makes it clear that this method of treatment has a training effect and results in sustained improvement in walking when the stimulator is inactive (60,63,64). Researchers suspect that this training effect represents central nervous system reorganization rather than just peripheral improvements in muscle tone, range of motion, and muscle strength (64).

Another recent advance in the management of gait disorders associated with spasticity and dystonia has been the application of botulinum toxin (BTX) types A and B. BTX is available in the United States and many other countries for therapeutic use. When compared to other muscle tone-reducing options, these toxins have the advantage of producing selective, graded weakness in individual muscles with a predictable recovery over several weeks. Gait analysis may identify a muscle or muscles that reduce the efficiency of gait (65), and BTX can reduce the contractile force of the selected muscle. The analysis might be a simple, clinical observation of gait as part of a neurological exam, or it might be a sophisticated, multichannel EMG recording of muscle activity during the gait cycle. At the time of injection, needle electromyography may confirm motor unit activity at rest, or electrical muscle stimulation may be used to direct the injection into the muscle identified by the exam during walking.

An example of this type of treatment includes treatment of ankle inversion by BTX injection of the tibialis posterior muscle (in some cases with additional dosing of the tibialis anterior) (26). During the ensuing weeks, the weakened muscles will require orthotic support so that stable walking can be practiced (66); however, the treatment can reduce pressure at the lateral malleolus and other areas so that pain and pressure ulcers are improved. The result can include improved walking speed and step length (67,68). Adductor muscle scissoring of the thighs can also be improved with BTX treatment. A risk to be considered is the potential loss of extensor tone in the lower limbs upon which the patient has been relying for standing and walking. While the rehab team may be able to teach a compensation for this weakness, in many cases, the patient will need to wait for the BTX to wear off so that the useful tone returns to the legs. Dosing information for BTXs A and B are available for both adults and children (69,70). Typically, injections are repeated at 3 to 4 month intervals if the offending

muscle tone reoccurs (71). Side effects, in addition to muscle weakness or fatigue, include nausea or "flu-like symptoms" and symptoms associated with anticholinergics such as dry mouth. BTX treatment has eliminated the use of tendon transfer surgery for many patients (70). It needs to be noted, however, that BTXs have not yet been approved for this use by the U.S. Food and Drug Administration and that serious complications, including some deaths, have been reported. However, numerous authorities have produced practice guidelines for this therapy (69–72) and most U.S. health care plans pay for the treatment (73).

Treatment with BTX is an adjunct to other physical and pharmacologic treatment of specific conditions resulting in disordered muscle tone, covered in more detail in other chapters of this text. Oral and intrathecal baclofen therapies have been shown to improve walking velocity in appropriately selected patients with upper motor neuron disorders, for example (67,71). However, it should always be remembered that the primary treatment of abnormal tone is a consistent stretching exercise program (with active exercise as is practical for the individual) that improves the health of the muscles (69,70).

### Gait Abnormalities Associated with Aging

Many of the gait changes seen in elderly individuals may be attributed to their reduced walking speed (74,75). However, differences that persist when healthy elderly individuals walk both at comfortable walking speeds and at speeds comparable to those of young adults include reduced peak hip extension, increased anterior pelvic tilt, and reduced ankle plantar flexion and power generation, possibly caused by ankle plantar-flexor muscle weakness (75). Reduced gait velocity, resulting from reductions in both stride length and cadence, has been shown to correlate with lower-limb muscle strength in older persons, but the muscle group that is primarily responsible has been variably suggested to be the ankle dorsiflexors (76), ankle plantar flexors (77), knee extensors and hip flexors (78), and more recently, hip extensors (79).

Falls in the elderly may be due to a variety of factors impacting one or more of a number of organ systems related to balance, such as disturbances of the visual, vestibular, cognitive, sensory, and other systems. However, falls occur in elderly individuals without evident predisposing factors. Although kinematic gait studies have not revealed significant differences between fallers and nonfallers, kinetic gait studies have shown increased peak external hip flexion moment in stance, reduced peak hip extension moment, reduced knee flexion moment in preswing, and reduced knee power absorption in preswing phase (80).

## BODY WEIGHT–SUPPORTED TREADMILL TRAINING

We will conclude this chapter with a brief discussion of body weight–supported treadmill training (BWSTT), a more recently developed approach to gait rehabilitation being utilized with

increasing frequency for patients with diminished or absent supraspinal control. Although this technique was initially developed and then used with varying degrees of success following SCI (81–88), BWSTT has since been a component of locomotor rehabilitation for patients with stroke, traumatic brain injury (TBI), Parkinson's disease, and lumbar stenosis (89–99), among other conditions. In addition, improvement in cardiovascular fitness from BWSTT has been documented in patients after a stroke or TBI (100–102).

BWSTT employs upright walking on a motorized treadmill while the patient wears a suspension harness to reduce ground reaction force (or GRF) by a specified percentage. Typically, two therapists (and sometimes a third to facilitate upright posture) manually position and guide each lower limb to achieve repetitive, rhythmic stepping motions. To reduce therapist effort and improve the repeatability of locomotor training, commercially available robotic devices have been developed to increase the volume of stepping practice (103–105). Another proposed technologic refinement in the setting of hemiparetic gait has been a computer-controlled, dynamic system to precisely regulate the magnitude and timing—with respect to gait cycle events—of body weight support provided to the user (106).

# Imaging Techniques Relative to Rehabilitation

A brief presentation of imaging techniques of interest to the physiatrist must necessarily be selective. Because the diagnosis and initial treatment of fractures are primarily the responsibility of the orthopedic surgeon, with the rehabilitation professional typically involved only later in the course, a full discussion of fractures is not presented in this chapter. Only those fractures that bring patients under the long-term care of the physiatrist are included (e.g., vertebral fractures with the potential to damage the spinal cord). Similarly, tumors and infectious processes are de-emphasized. Rather, emphasis is placed on imaging degenerative musculoskeletal processes, spine and head trauma, stroke, and degenerative central nervous system (CNS) diseases commonly seen by the physiatrist. We will also cover imaging in sport medicine as this is a rapidly changing area in radiology and review the current applications of diagnostic ultrasound in the evaluation of musculoskeletal disorders.

In the past two decades, computed tomography (CT) and magnetic resonance imaging (MRI) have become the most sophisticated imaging modalities for evaluating the musculoskeletal system and the CNS. Therefore, this chapter focuses mainly on the recent applications of CT and MRI in the imaging of musculoskeletal and neural pathology of interest to the physiatrist. In the final section, we will introduce some relatively new imaging technologies of interest to the physiatrist, including advanced MRI methods and ultrasound imaging (USI).

The role of plain film examinations in the assessment of abnormalities of specific joint disorders is well established in the medical literature. A brief review of the most commonly performed radiographic examinations of the extremities will be done when addressing the specific subject.

## MUSCULOSKELETAL IMAGING

The advent of the multidetector CT (MDCT) scanner has increased the applicability of this imaging technique for the assessment of the musculoskeletal system. This technology allows for the acquisition of large data set in the axial plane that can be reconstructed in multiple planes of imaging with the use of multiplanar reconstruction (MPR) algorithm.

Any anatomical part in the human body can now be scanned in the axial plane and the anatomical information can later be reconstructed in the sagittal, coronal, or any orthogonal plane desired in order to better assess complex anatomical structures such as the joints of the axial skeleton and the spine (1).

CT provides poor contrast resolution to evaluate the musculoskeletal system. Since the relative soft-tissue density of cartilage, tendons, and muscle is similar, we cannot resolve adequate soft-tissue differences between these structures. For example the articular cartilage can only be assessed with CT after a positive contrast is introduced in the joint space such as is the case with CT arthrography. CT however provides a superb spatial resolution that allows for the accurate evaluation of fine soft-tissue and bone trabecular details.

CT images may be displayed with various windows suitable to resolve different structures. Bone window images provide the highest resolution of compact and cancellous bone. Soft-tissue window offers moderate resolution of muscle, tendon, ligament, fat, cartilage, and neural structures.

The good resolution and enhanced contrast of MRI for soft-tissue structures, together with its direct multiplanar imaging capability, make it a superb modality for evaluating all the principal constituents of the musculoskeletal system. Although a technical discussion of the physics of MRI is beyond the scope of this chapter, the physiatrist should know the normal and abnormal MRI appearance of various tissues to be able to look at an MR image with confidence and explain the findings to a patient. The MRI signal intensity of any tissue primarily reflects its proton density, its T1 relaxation time, and its T2 relaxation time. Various techniques, including manipulating the repetition time (TR) between the application of radiofrequency pulses or the echo time (TE) between the radiofrequency pulse and the recording of a signal (i.e., echo) produced by the tissue, can emphasize the proton density, T1 relaxation time, or T2 relaxation time features of any tissue (2). The TR and TE are expressed in milliseconds. The most commonly used technique is spin echo, in which short TR and TE will emphasize the T1 relaxation time of a tissue, the so-called T1-weighted image. In general, an image is said to be T1 weighted if TR is less than 1,000 ms and TE is less than 30 ms (e.g., TR = 500 ms, TE = 20 ms). A T2-weighted image

**FIGURE 6-1.** Normal shoulder MR images. **A:** An axial scout film with cursors displays the oblique coronal planes parallel to the plane of the scapula, which allow optimal visualization of the supraspinatus. **B:** An oblique coronal image demonstrates the supraspinatus muscle belly (SsB), supraspinatus tendon (SsT), subacromial-subdeltoid fat plane (FP), acromioclavicular joint (ACJ), deltoid muscle (D), articular cartilage of humeral head and glenoid (AC), glenoid (G), and humeral head (H). **C:** An axial image displays humeral head (H), glenoid (G), glenoid labrum (L), the inferior glenohumeral ligament (IGL), deltoid muscle (D), subscapularis tendon (ScT), and biceps tendon (BT). **D:** A sagittal section demonstrates good resolution of the coracoacromial ligament (CAL) extending from the coracoid process (CP) to the acromion; coracoid process (CP), supraspinatus (SS), infraspinatus (IS).

generally is accomplished with a TR longer than 1,500 ms and a TE greater than 60 ms (e.g., TR = 2,000 ms, TE = 85 ms). Proton density images are obtained with a long TR and a short TE (e.g., TR = 2,000 ms, TE = 20 ms).

Most normal tissues demonstrate similar signal intensities on both T1- and T2-weighted images. Compact bone, fibrocartilage, ligament, tendon, and the rapidly flowing blood within the blood vessel typically produce very low signal intensity, referred to as a *signal void*, and appear black both on T1 and T2 (Fig. 6-1). Muscle demonstrates moderately low signal intensity and appears dark gray. Peripheral nerves demonstrate slightly higher signal intensity than muscle because of the fat content of their myelinated fibers. Hyaline cartilage produces

moderate signal intensity and appears light gray. Fat produces very high signal intensity and appears bright on T1 and T2. Because fat is frequently situated adjacent to ligaments and tendons, it can provide a high-contrast interface for evaluating the integrity of these structures. Adult bone marrow also shows high signal intensity because of its high fat content. Most normal body fluids that are not flowing show low signal intensity on T1-weighted images and high signal intensity on T2-weighted images.

Pathologic processes such as tumor, infection, and abnormal fluids (e.g., edema, joint effusion) show intermediate signal intensity on T1-weighted images and become very hyperintense on T2-weighted images. Pathologic calcifications

demonstrate very low signal intensity on both T1- and T2-weighted images.

The direct multiplanar imaging capability of MRI is particularly useful in evaluating obliquely oriented musculoskeletal structures such as the supraspinatus tendon, the cruciate ligaments, and the lateral collateral ligaments of the ankle.

MRI has proved useful in evaluating traumatic, degenerative, inflammatory, and neoplastic pathology of the limbs and spine. It is useful in detecting acute or chronic traumatic injuries and degenerative conditions involving bones, muscles, tendons, ligaments, fibrocartilage, and nerves. Bone pathology, particularly well detected by MRI, includes contusions, osteochondral injuries, stress fractures, marrow replacement by neoplastic cells, and ischemic necrosis. Muscle lesions that MRI is especially sensitive at identifying include strain or contusion, complete rupture, compartment syndrome, myopathies, and atrophy (3). Tendon conditions well depicted by MRI include partial and complete tear, tendinitis, and tenosynovitis. MRI is also very sensitive for detecting partial or complete ligament tears. Fibrocartilaginous injuries or diseases well delineated by MRI include pathology of the menisci, the glenoid labrum, the triangular fibrocartilage of the wrist, and the intervertebral disc. Nerve entrapments well visualized by MRI include spinal nerve encroachment by disc disease or spinal stenosis and carpal tunnel syndrome (CTS) or other entrapment syndromes. Enhanced imaging of normal and injured peripheral nerves can be obtained using a short-tau inversion recovery (STIR) excitation-emission sequence due to the increased sensitivity to free water content associated with tissue edema using this MR recording protocol. The increased signal generated by injured nerves using STIR pulse sequences probably reflects an increase in free water content of the nerve due to altered axoplasmic flow, axonal and/or myelin degeneration, and endoneurial or perineurial edema due to a breakdown in the blood-nerve barrier (4). MRI imaging of denervated skeletal muscle shows increased MR signal using the STIR protocol when there is significant muscular weakness and well-defined changes indicating muscle denervation on needle electromyography (5).

Osteomyelitis causes a reduction in bone marrow signal intensity on T1-weighted images because of the replacement of normal fatty marrow by inflammatory exudate. In T2-weighted images, these areas of active infection become hyperintense.

MRI has particular value in evaluating both bone and soft-tissue neoplasms. Most of them demonstrate moderately low signal intensity on T1-weighted images and very high signal intensity on T2-weighted images.

Emphasis will now be directed to the application of imaging modalities to common regional pathologic conditions of the musculoskeletal system. Particular focus will be given to MRI because of its superb soft-tissue imaging capabilities and its rapidly expanding diagnostic applications.

The important role played by radiology in the diagnosis of diseases has come at the expense of increased radiation exposure to the general population. With the advent of new technology, such as Positron Emission Tomography (PET) studies

and MDCT technology, there has been a sharp increase in the number of radiographic examinations performed to the general population and as a consequence an increase in the cumulative radiation dose to the individual patient and the general population. It is an expected outcome for increase in radiation exposure to lead to an increased rate of malignancy. Therefore, increased awareness is needed in issues concerning radiation safety.

Ionizing radiation, especially at high doses, is known to increase the risk of developing cancer. It is estimated that medical exposure might be responsible for 1% of cancer diagnosis in the United States. This rate is expected to increase in the coming years due to the increased number of examinations performed today.

The scientific measurement for the effective dose of radiation is the millisievert (mSv). The background radiation dose for the average person in the United States is about 3 mSv. This is secondary to cosmic radiation and naturally occurring radioactive materials. By comparison, the effective radiation dose for a spinal CT is equivalent to 6 mSv or 2 years of natural background radiation. Radiation exposure is particularly important in pregnant women and pediatric patients due to the cumulative life effect of radiation exposure at a younger age. In nuclear medicine examinations, special precautions are needed. Some of the radiopharmaceuticals used in nuclear medicine can pass into the milk of lactating women (6).

The relative radiation level (RRL) is a radiation measurements used to calculate effective dose. This is the dose used to estimate population total radiation risk associated to an imaging procedure. This takes into account the sensitivity of different body organs and tissues. This estimate cannot assess the specific risk of an individual patient.

Every effort should be made to order examination, which is best indicated to address the clinical concern of the patient. To aid in this regard, the American College of Radiology ([acr.org](http://www.acr.org)) has established guidelines for the appropriate use of imaging to answer specific clinical questions. The appropriateness criteria can be of help when deciding which imaging study to order to answer a clinical question.

## Shoulder

Plain film radiographic evaluation of the shoulder should include frontal examinations with internal and external humeral rotation. If there is a question of instability or dislocation, an axillary view, a scapular Y view, or both should be obtained. There have been several reports that recommend the use of a 30-degree caudad-angled radiograph or a suprascapular outlet view for the assessment of the anterior acromion in cases of suspected shoulder impingement. Since these are special views, they must be ordered as routine shoulder radiographs do not include axillary or suprascapular outlet views. The RRL for plain film radiographic examinations of the shoulder is less than 0.1 mSv, which is considered minimal.

MRI has become valuable in evaluating a host of shoulder abnormalities very familiar to the physiatrist. These include impingement syndrome, other rotator cuff abnormalities, instability syndrome, and bicipital tendon abnormalities. It is

also useful in demonstrating arthritic changes, occult fractures, ischemic necrosis, and intra-articular bodies. MRI with intra-articular contrast is now considered the modality of choice for the evaluation of labral and capsular pathology. The use of MRI for shoulder evaluation avoids radiation exposure to the nearby thyroid gland, which can occur with CT examinations. The excellent visualization of marrow by MRI permits early diagnosis of ischemic necrosis, infection, and primary or metastatic tumors.

Because of the oblique orientation of the scapula on the chest wall and the consequent anterolateral facing direction of the glenoid, the direct multiplanar imaging capability of MRI provides optimal visualization of all the important shoulder structures. An oblique coronal image parallel to the plane of the scapula provide full-length views of the rotator cuff musculature, especially the supraspinatus and is the best plane for the evaluation of injuries to the biceps-labral complex (BLC) (Fig. 6-1A and B). Coronal oblique images can also provide information about the presence of impingement upon the supraspinatus by the acromion and osteophytes in the presence of acromioclavicular joint osteoarthritis. Oblique sagittal imaging planes parallel to the glenoid provide cross-sectional views of the rotator cuff apparatus and evaluates the anatomical configuration of the coracoacromial arch and the presence of impingement (Fig. 6-1D). Axial imaging planes provide good visualization of the anterior and posterior capsular apparatus, glenoid labrum, bony glenoid rim, and humeral head (Fig. 6-1C).

## SHOULDER IMPINGEMENT SYNDROME AND SUPRASPINATUS INJURY

The MRI findings of shoulder impingement syndrome and its associated supraspinatus injury are best seen on oblique coronal MR images that visualize the full length of the

supraspinatus muscle belly and tendon (Fig. 6-1B). The normal muscle belly displays moderately low signal intensity. The tendon is visualized as an intermediate-signal-intensity structure that blends with the low signal intensity of the superior capsule as it courses to its insertion on the greater tubercle of the humerus. The tendon demonstrates smooth tapering from medial to lateral into its insertion in the greater tuberosity. The inferior aspect of the tendon is delimited below by the moderate signal intensity of the hyaline cartilage on the superior aspect of the humeral head. The superior aspects of both the muscle belly and tendon are delimited by a high-signal-intensity subacromial and subdeltoid fat plane. The normal subacromial-subdeltoid bursa is not specifically visualized because its walls are separated only by monomolecular layers of a synovial-type fluid, but it is situated between the supraspinatus tendon and the fat plane. Above the fat plane, the clavicle, acromioclavicular joint, acromion, and deltoid muscle are demonstrated on different oblique coronal sections.

Although rotator cuff impingement is a clinical diagnosis, MRI can provide direct visualization of the constituents to the coracoacromial arch and their relationship to the supraspinatus (Fig. 6-2A and B). Downward slanting of the acromion in the coronal or the sagittal plane, a thickened coracoacromial ligament or inferior osteophytosis within the acromioclavicular joint can exert mass effect upon the supraspinatus. This has been implied as being in part responsible for chronic tears of the supraspinatus.

Neer stated that 95% of rotator cuff tears are associated with chronic impingement syndrome (7) and described three stages in the progression of rotator cuff injury. These can be visualized by MRI (6–10). Stage 1 is characterized by edema and hemorrhage within the supraspinatus tendon characteristic of an early tendinitis. On MRI, there is focal tendon

**FIGURE 6-2.** **A:** Coronal oblique T2-weighted pulse sequence with fat suppression demonstrates downward slanting to the acromion (*long arrow*), which is against the supraspinatus tendon (\*). Note focal area of increased signal at the myotendinous junction of the SsT (*short arrow*). **B:** Sagittal oblique T2WI with fat suppression demonstrates to a better advantage the inferior slanting to the acromion against the SsT (*short arrow*). Note focal tendinosis (*long arrow*).

**FIGURE 6-3.** **A:** T1-weighted MRI of focal supraspinatus tendinosis demonstrating focal thickening and slight increase signal intensity to the tendon (*arrow*). **B:** Coronal oblique T2-weighted fat suppressed sequence with increased signal intensity within the area of tendinosis (*arrowhead*). There is fluid within the adjacent subdeltoid bursa (*long arrow*). **C:** Sagittal oblique T2-weighted fat suppressed image demonstrates the area of increased signal to be within the anterior superior portion of the rotator cuff representing fibers of the supraspinatus tendon (*short arrow*).

thickening and diffuse moderate increase in signal intensity within the tendon (Fig. 6-3A–C). In stage 2, Neer described both inflammation and fibrosis within the tendon. MRI shows this as thinning and irregularity of the tendon. Stage 3 is a frank tear of the supraspinatus tendon. On MRI, complete tears are noted by a discontinuity of the tendon with a well-defined focus of high signal intensity on T2-weighted images (Fig. 6-4). The most susceptible area is the critical zone of hypovascularity, located about 1 cm from the insertion (11). With small or partial tears, there is no retraction of the muscle-tendon junction, the subacromial-subdeltoid fat plane is commonly obliterated, and fluid may accumulate in the subacromial-subdeltoid bursa, which becomes hyperintense on T2-weighted images. There also may be effusion of the shoulder joint, which may extend inferiorly along the tendon sheath about the long head of the biceps. With a complete supraspinatus tendon tear, the muscle belly may retract medially, and atrophy may occur as the tear becomes chronic (Fig. 6-5A,B). Muscle atrophy appears as areas of high signal

**FIGURE 6-4.** Complete rupture of the supraspinatus tendon is seen in a T2-weighted MRI. There is fluid filling the gap (*arrow*) and there is retraction to the tendon fibers underneath the acromion.

**FIGURE 6-5.** Complete rotator cuff tear. **A:** Coronal oblique T1-weighted image. There is intermediate signal intensity (\*) from the inflammatory reaction replacing the normal low signal to the SS tendon. **B:** The edge (arrow) to the retracted tendon is at the level of the superior labrum. There is increased signal intensity filling the gap of the retracted tendon (long arrow).

intensity because of fatty replacement within the muscle belly and decreased muscle mass. Finally, the acromiohumeral interval narrows as the humeral head migrates superiorly, because of the loss of supraspinatus restraint to the deltoid's tendency to sublux the humerus superiorly during abduction.

## SHOULDER INSTABILITY AND DISRUPTION OF THE ANTERIOR CAPSULAR MECHANISM

For the assessment of shoulder instability and labral tears, it is imperative that intra-articular contrast medium be injected in order to be able to evaluate the entire articular labrum, glenoid fossa, and capsular mechanism (12). Axial MR images provide the best visualization of the anterior and posterior glenoid labra, capsule, and lower rotator cuff muscles (Fig. 6-1). Anteriorly, the moderate-signal-intensity subscapularis muscle belly and its low-signal-intensity tendon are visualized. The tendon fuses with the low-signal-intensity anterior capsule as it courses to its insertion on the lesser tubercle. The fibrocartilaginous anterior and posterior labra appear as low-signal-intensity triangular or rounded areas attached to the glenoid rim. The higher-signal-intensity intra-articular contrast opposed the hyaline cartilage surfaces of the glenoid and humeral head. The posterior capsule is visualized as a low-intensity area blending with the deep surface of infraspinatus and teres minor muscles as they extend to their insertions on the greater tubercle of the humerus. The long tendon of the biceps is demonstrated as a round, low-signal-intensity area within the bicipital groove.

Shoulder instability and the associated disruption of the anterior capsular mechanism can cause chronic shoulder pain and disability. The instability may be caused by an acute traumatic

episode or can occur with no history of a traumatic event. Both recurrent traumatic subluxation and nontraumatic instability are typically associated with disruption of the anterior capsular mechanism. Anteriorly, where most instability occurs, this mechanism includes the subscapularis muscle and tendon, the anterior joint capsule, three underlying glenohumeral ligaments, the synovial lining, and the anterior labrum. With instability, the labrum shows tears, separation from the glenoid rim, or degeneration (13). Also frequently present are medial stripping of the capsule from its normal attachment to the labrum and glenoid rim, an enlarged fluid-filled subscapular bursa secondary to joint effusion, attenuation of the glenohumeral ligaments, and injury or laxity of the subscapularis muscle or tendon.

By MRI, labral tears may be visualized as discrete linear areas of increased signal intensity within the normal signal void of the labrum (Figs. 6-6 and 6-7). These areas show moderate intensity on T1-weighted images and high intensity on T2-weighted images. With recurrent dislocation or subluxation, the labrum can become fragmented or attenuated.

Capsular detachment from the scapula (i.e., stripping) is visualized by T2-weighted MRI as an area of high-signal-intensity fluid dissecting medially from the glenoid rim. With trauma to the subscapularis tendon, there can be medial retraction of the muscle-tendon junction when the tendon is completely ruptured. Chronic atrophy of the subscapularis muscle belly is identified by high-signal-intensity fatty replacement. The glenoid marrow underlying a labral detachment may show pathologically decreased signal intensity even before the plain film radiograph shows an osseous Bankart lesion. MRI and CT can be used to visualize Bankart fractures of the anterior glenoid and the Hill-Sachs compression deformity of the posterolateral humeral head (14,15) and are both useful in the assessment

**FIGURE 6-6.** SLAP lesion and posterior labral tear in a patient with history of posterior instability. **A:** Coronal oblique T1-weighted fat suppressed MR arthrogram demonstrates increased signal intensity within the BLC extending on the biceps tendon (*arrowhead*) characteristic of a type IV SLAP lesion. **B:** Axial T1-weighted MR arthrogram demonstrates increased signal within the posterior labrum (*arrowhead*). There is a cyst within the posterior aspect of the spinoglenoid notch with high-signal-intensity contrast extending into the cyst.

of the extent of a Hill-Sachs defect in patients with engaging lesions. Patients with the rarer posterior instability show similar posterior labral, capsular, and muscular defects.

### TENDINITIS OR RUPTURE OF OTHER SHOULDER MUSCLES

Tendinitis and rupture also can involve the subscapularis, infraspinatus, and teres minor, or biceps tendons, although far less commonly than the supraspinatus. Early tendinitis involves

an increased signal intensity area within the tendon. This can progress to frank rupture of the tendon with a high-signal-intensity area at the site of the tear on T2-weighted images and may be associated with joint effusion. A complete tear will eventually cause muscle retraction and later atrophy.

Calcific tendinitis (Fig. 6-8) of the supraspinatus is a common clinical entity most commonly affecting middle age persons. It is slightly more common in females and can affect multiple tendons in the body. It is however far more frequently in the supraspinatus. Although the exact etiology is unknown, it is felt to be secondary to chronic ischemia of the tendon fibers.

**FIGURE 6-7.** Bankart lesion. **A:** Axial T1-weighted images of a left shoulder MR arthrogram demonstrate the fibrocartilaginous Bankart lesion of the anterior glenoid labrum (*arrow*). **B:** Coronal T1-weighted fat suppression demonstrates the inferior (*short arrow*) and the superior (*long arrow*) extensions of the labral tears.

**FIGURE 6-8.** Calcific tendinosis of the infraspinatus tendon. **A:** Axial T1WI and **B:** coronal oblique T2WI with fat suppression demonstrating a focal area of decreased signal within the fibers of the distal infraspinatus (arrow). Note high-signal-intensity fluid within the posterior joint (\*). **C:** Sagittal oblique T1WI shows the calcification within the posterior fibers of the infraspinatus.

Increased high-intensity fluid about the biceps tendon on T2-weighted MR images can be produced by either a biceps tenosynovitis or a shoulder joint effusion because the tendon sheath normally communicates with the shoulder. Rupture of the biceps tendon is demonstrated by absence of the biceps tendon within the intertubercular sulcus and by distal retraction of the muscle, which is seen on imaging the arm (16). Dislocation of the biceps tendon is identified by medial displacement of the biceps tendon out of the intertubercular sulcus.

### ISCHEMIC NECROSIS OF THE HUMERAL HEAD

As in other joints, ischemic necrosis of the humeral head is depicted as an area of decreased signal intensity within the subarticular bone marrow in T1-weighted images. On T2-weighted images, curvilinear bright bands surrounding areas of decreased signal intensity, the so-called tram track sign, represent reactive marrow surrounding the core of dead

bone. Ischemic necrosis is more fully described with the hip, where its incidence is higher.

### ELBOW

Plain film radiographic examination of the elbows should be the initial evaluation for patients with chronic elbow pain. Radiographs can be useful for the assessment of calcium within the joint compartment or periarticular soft tissues. Standard frontal and lateral radiographs are used for the routine evaluation of the elbow joint. Radiographic examination of the elbow has a minimal RRL.

MRI has not been applied to the evaluation of elbow pathology as extensively as it has been to other large joints (17). However, improving imaging techniques and the use of surface coils permit superb visualization of the bony, ligamentous, muscular and neurovascular structures around the elbow. Common elbow injuries evaluated with MRI are usually related to sports (weightlifting, throwing, and racquet sports) or compartmental nerve entrapment.

**A****B****C**

**FIGURE 6-9.** Normal elbow as seen on T1-weighted MR images. **A:** The axial MRI displays the ulna (U), radius (R), annular ligament (AL), radial collateral ligament (RCL), brachial artery (BA), biceps tendon (BT), forearm flexor muscles (FM), forearm extensor muscles (EM), ulnar nerve (UN), and radial nerve (RN). **B:** The coronal MRI displays the humeroulnar joint (HUJ), humero-radial joint (HRJ), radial collateral ligament (RCL), ulnar collateral ligament (UCL), forearm flexor muscles (FM), and forearm extensor muscles (EM). **C:** The sagittal MRI through the humeroulnar joint demonstrates the biceps tendon (BT), brachialis (Br), and triceps (T).

Axial MRI views of the elbow region permit good visualization of the biceps, brachialis, triceps, and all the extensor and flexor muscles of the forearm (Fig. 6-9A). High-signal-intensity fat planes and low-signal-intensity intermuscular septa permit clear delineation of each muscle and their tendons of insertion or origin. Axial images clearly depict brachial, ulnar, and radial arteries and all the subcutaneous and deep veins. They also allow identification of the ulnar nerve within the cubital tunnel and the radial nerve in the brachioradialis-brachialis interval and under the supinator muscle's arcade of Frohse, where it is commonly entrapped. The median nerve is visualized at all its common elbow entrapment sites, including under the bicipital aponeurosis, between the heads of the pronator teres, and under the fibrous arch of the flexor digitorum superficialis.

The humeroulnar, humeroradial, and proximal radioulnar joint spaces and articular cartilages are well visualized on both coronal and sagittal MR images (Fig. 6-9B and C). The low-signal-intensity ulnar collateral, radial collateral, and annular ligaments are depicted on both axial and coronal MR

images. Sagittal images delineate the anterior and posterior subsynovial fat pads.

MRI has the capability of directly visualizing degenerative or traumatic abnormalities of the annular and the radial and ulnar collateral ligamentous complexes. A sprain appears in MRI as thickened or thinned ligament with surrounding high T2 signal intensity. The collateral ligaments may show degeneration in association with adjacent epicondylitis. The affected ligament commonly shows thickening and intermediate signal intensity. Full thickness of avulsion ligamentous tears appears as discontinuities of the low-signal-intensity ligament. The T2-weighted images disclose hyperintense edema and hemorrhage between the torn ends of the ligament extending into the joint interval and adjacent soft tissues. A partial thickness tear appears as high T2 fluid signal intensity within an uninterrupted ligament (Fig. 6-10).

MRI also provides good visualization of the sites of muscle injury and denervation about the elbow (18) (Fig. 6-11A,B). Acute muscle denervation is demonstrated by increased T2-weighted signal intensity within the specific muscle

**FIGURE 6-10.** Coronal MR T1WI with intra-articular contrast in a 22-year-old baseball player with medial elbow pain. There is a partial tear (*arrowhead*) at the insertion of the ulnar collateral ligament into the coronoid process of the ulna. Note the minimal amount of contrast extending between the bone cortex and the distal ligament attachment.

group supplied by the injured or the affected nerve. Increased intramuscular T2-weighted signal intensity is due to muscle edema. Chronic muscle denervation is demonstrated by increased intramuscular T1-weighted signal intensity, related to muscle atrophy and fatty infiltration. Acute muscle injuries presents with intramuscular edema and hemorrhage. Increased

**FIGURE 6-11.** Impingement to the anterior interosseous branch of the median nerve, Kiloh Nevin Syndrome. Axial STIR (short tau inversion recovery sequence) at the level of the distal forearm. On this fat suppressed sequence there is increased signal intensity to the fibers of the flexor pollicis longus muscle as can be appreciated with acute (stage I) or subacute (stage II) impingement. (Courtesy of Zehava Rosenberg, NY.)

thickening, increased signal intensity, and discontinuity of tendon fibers are the findings commonly observed in tendon tears (Fig. 6-12A,B).

MRI has the ability to demonstrate tendinosis involving the common extensor and flexor tendon origins from the lateral and medial aspects of the humerus with findings similar to those described in tendinosis about the shoulder. It also can display abnormalities of the radial and ulnar collateral ligament complexes.

## Wrist

Plain film radiography and CT provide good visualization of the osseous structures of the wrist. Most physicians agree that the imaging evaluation of a painful hand and wrist should begin with radiographs. This inexpensive study may establish a specific diagnosis in arthritis, injury, infection, and wrist instability. Standard anteroposterior (AP) and lateral radiographs of the wrist are enough for most clinical presentations (19). Additional views can be ordered to assess specific clinical problems, such as scaphoid views in patients with trauma and pain in the snuffbox. In the specific setting of wrist trauma, further imaging studies should be considered in the presence of negative radiographic examinations due to the high incidence of missed occult fractures. The relative radiation dose for radiographic examinations of the wrist is low. The ability of MRI to visualize soft-tissue pathology already has been shown to be of great value in assessing CTS and may prove useful in imaging cases of unexplained wrist pain (20–22). MR arthrography provides detailed information about ligamentous disorders in and about the wrist.

Axial MR images through the wrist from the distal radioulnar joint to the metacarpals provide excellent visualization of all the bones, joints, ligaments, muscles, tendons, nerves, and vessels in the wrist area (Fig. 6-13A–D). They also clearly display all the boundaries and contents of the carpal tunnel and Guyon's canal.

## CARPAL TUNNEL SYNDROME

MRI can serve as an adjunct diagnostic tool for CTS when the clinical or neurophysiologic findings are equivocal. The carpal tunnel is a fibro-osseous space with little fat that contains the flexor tendons and the median nerve. The flexor retinaculum composes the volar aspect of the tunnel and normally shows slight palmar bowing. The median nerve courses through the tunnel within its volar and radial aspect, and it can be differentiated from the adjacent tendons because it shows relative higher signal intensity. The carpal tunnel and its contents are best evaluated in the axial plane and should be scrutinized at three standard locations.

1. Distal radioulnar joint before the median nerves enter the tunnel.
2. Proximal tunnel, at the level of the pisiform.
3. Distal tunnel, at the level of the hook of the hamate.

**FIGURE 6-12.** Sagittal A and axial B FSE T2-weighted fat suppressed images of the distal arm in a patient with a complete biceps tear. **A:** The tendon free margin is retracted (*long arrow* in A). **B:** There is significant edema (*arrowheads*) surrounding the retracted tendon (*long arrow*). B, biceps muscle; Br, brachialis muscle.

**FIGURE 6-13.** Normal wrist anatomy as seen on T1-weighted MR images. Axial MR images are at the levels **A:** of the distal radioulnar joint, **B:** the proximal and **C:** the distal carpal tunnel. **D:** Longitudinal MRI through the median nerve within the carpal tunnel. C, capitate; FDP, flexor digitorum profundus; FDS, flexor digitorum superficialis; FR, flexor retinaculum; H, hamate; L, lunate; MN, median nerve; PDN, palmar digital branches of the median nerve; R, radius; T, trapezium; U, ulna; UA, ulnar artery; UN, ulnar nerve. Note fracture through the base of the hook of the hamate (*arrow* in B).

There are four universal findings of CTS visible by MRI regardless of etiology (21):

1. Swelling of the median nerve (i.e., pseudoganglion) in the proximal part of the carpal tunnel at the level of the pisiform. Best evaluated by comparing the size of the median nerve at the level of the distal radioulnar joint with its size at the proximal tunnel.
2. Increased signal intensity of the edematous median nerve on T2-weighted images.
3. Palmar bowing of the flexor retinaculum, determined by a bowing ratio of more than 15%. The bowing ratio is calculated by drawing a line from the trapezium to the hook of the hamate on the axial plane. The distance from this line to the flexor retinaculum is divided by the previously calculated length.
4. Flattening of the median nerve in the distal carpal tunnel at the level of the hamate (Fig. 6-14A–D).

MRI also has the potential to establish the cause of CTS. Some of the etiologies visualized by MRI include traumatic tenosynovitis, rheumatoid tenosynovitis, a ganglion cyst of a carpal joint, excessive fat within the carpal tunnel, a hypertrophied adductor pollicis muscle in the floor of the carpal tunnel, and a persistent median artery (23).

MRI also provides a means of postoperative evaluation of those patients in whom the symptoms persist, to ensure that the flexor retinaculum has been completely incised and that there are no other complicating postoperative factors producing continuing discomfort. When the flexor retinaculum has been completely incised, the incision site is well documented by MRI and the contents of the carpal tunnel are typically displaced forward (Fig. 6-15A). If the distal part of the flexor retinaculum has been incompletely incised, this can be demonstrated by MRI, and the preoperative MRI findings of CTS will persist (Fig. 6-15B and C).

**FIGURE 6-14.** Axial FSE T2-weighted fat suppressed images (**A**, **B**, **C**) and sagittal T1-weighted image in a patient with carpal tunnel syndrome. **A**, **B**: There is a normal size to the nerve within the tunnel (*arrowheads*). **C**: There is thickening, increased girth and increased signal intensity proximal to the flexor retinaculum (*arrowheads*). **D**: Note tapering to the nerve as it approaches the carpal tunnel in the sagittal view (*arrowheads*).

The median nerve (*arrow*) has intermediate signal and is better delineated. **C:** Patient with failed carpal tunnel release. There is a linear area of decreased signal intensity (*short arrow*) which was found to represent a fibrous band at surgery. The median nerve (*long arrow*) is flattened underneath the fibrous band. (**A** and **B**; courtesy of Zehava Rosenberg, NY. **C**; courtesy of Mark Kransdorf, FL.)

## OTHER WRIST ABNORMALITIES

MRI can visualize postincisional neuromas as lobulated masses in the typical location of the palmar cutaneous branches of the median nerve. Other peripheral nerve tumors such as schwannomas (Fig. 6-16) and neurofibromas can be well recognized as well. It can also demonstrate tenosynovitis involving any of the tendons crossing the wrist. MRI also displays marrow abnormalities such as ischemic necrosis of the proximal fragment of a scaphoid fracture and avascular necrosis of the lunate, where the marrow shows reduced signal

intensity (24). MRI has the ability to evaluate the integrity of the intrinsic/extrinsic ligaments of the wrist and the triangular fibrocartilage complex (TFCC) (25). The TFCC, scapholunate, and lunotriquetral ligaments are best evaluated with MR arthrography (Fig. 6-17).

## Hip

Similar to the remaining joints in the body, plain film radiographic examinations should be the first diagnostic test in patients with chronic hip pain. Frontal and frog leg views

**FIGURE 6-16.** Coronal T2-weighted sequence in a 72-year-old patient with a palpable hypothenar mass. There is a rounded soft tissue mass (arrow) within the ulnar nerve proximal to the retinaculum representing a schwannoma of the ulnar nerve. Courtesy of Dr. Mark Kransdorf, Jacksonville Fla.

are the standard radiographs performed for the assessment of hip joint abnormalities (26). The presence of osteoarthritis, bone tumors, and soft-tissue calcifications can be assessed

**FIGURE 6-17.** A coronal T1-weighted image of the wrist shows intermediate signal intensity and increased distance to the scapholunate interval (arrow), representing a scapholunate ligament tear.

with plain films. Special radiographic views are useful in the assessment of particular clinical problems. Patients suspected of femoroacetabular impingement can benefit from cross table lateral radiographs of the hip joint.

MRI of the hip is usually performed in standard axial, coronal, and sagittal planes; although oblique axial images are commonly used in routine protocols. The normal marrow of the femoral head epiphysis and the greater trochanter displays very high signal intensity and is surrounded by a thin layer of compact bone that appears as a signal void. However, in children and young adults, the marrow of the femoral neck and shaft normally shows lower signal intensity, because it contains some residual hematopoietic marrow. The acetabulum has imaging characteristics similar to those of the femoral neck. The periphery of the hip joint interval displays the moderate signal intensity of the apposed hyaline cartilage surfaces of the femoral head and acetabulum, whereas the centrally situated acetabular notch contains high-signal-intensity fat. The thick, very-low-signal-intensity hip joint capsule blends with the acetabular labrum proximally and the cortex of the femoral neck distally. All the muscles, nerves, and blood vessels crossing the hip are well visualized.

## ISCHEMIC NECROSIS

One of the common indications for MRI of the hip is to determine the presence of ischemic necrosis. This is bone death produced by a compromised blood supply. It also has been called *avascular necrosis*, *osteonecrosis*, or *aseptic necrosis*. Predisposing factors that should raise the physician's index of suspicion include corticosteroid therapy, alcoholism, known hip trauma, chronic pancreatitis, Gaucher's disease, sickle cell disease, exposure to hypobaric conditions, subcapital fractures, childhood septic arthritis or osteomyelitis of the hip, and congenital hip dislocation (27). If undetected early, the disease can progress and finally undergo irreversible collapse of the femoral head. MRI has been demonstrated to be even more sensitive and specific than bone scintigraphy for the early diagnosis of ischemic necrosis of the femoral head (28–31).

On T1-weighted MRI, the foci of ischemic necrosis of the femoral head appear as homogeneous or heterogeneous well-delimited or diffuse areas of decreased signal intensity in the shape of rings, bands, wedges, or crescents, or in an irregular configuration (Fig. 6-18A–C) (32–33). The low signal intensity is caused by death of marrow fat and replacement of the marrow by a fibrous connective tissue. Some cases show a lower signal band surrounding the lesion, and this has been attributed to healing sclerotic bone at the interface between normal and necrotic bone. On T2-weighted images, many cases show a double-line sign with a high-signal-intensity zone just inside of a low-signal-intensity margin. This is thought to be produced by granulation tissue surrounded by sclerotic bone (31–33).

**FIGURE 6-18.** **A:** Frontal radiograph on patient with advanced left hip AVN. There is sclerosis to the femoral head and collapse (*arrow*) to the articular surface. Bilateral ischemic necrosis of the femoral head in a different patient. **B:** coronal T1-weighted, serpiginous areas of decreased signal intensity are well demarcated within the subchondral marrow. **C:** coronal T2-weighted fat suppressed images. There is edema within the right femoral head (*arrowheads*) on the right femoral head. The left femoral heads demonstrates a serpiginous area of increased signal intensity. These findings are characteristic of AVN.

## FEMOROACETABULAR IMPINGEMENT

Femoroacetabular impingement is another cause of hip pain that may initially have a non-specific clinical presentation; however, a thorough physical evaluation should be able to identify this condition. Pain can be elicited on physical exam by passive movement of the thigh into full flexion, adduction, and internal rotation (34). Radiographs often help to identify anatomical variations such as dysplasia of the femoral neck (Fig. 6-19) or acetabular overcoverage. MR arthrography (Fig. 6-20) can be a helpful imaging study for evaluating the consequences of femoroacetabular impingement as well as thoroughly evaluating the abnormal anatomy. Intra-articular contrast helps to better delineate hyaline cartilage defects as well as labral tears. These findings, along with the clinical evaluation, help guide the appropriate treatment plan.

## OTHER HIP ABNORMALITIES

Transient regional osteoporosis presents with a low-signal-intensity lesion on T1-weighted images that is similar to ischemic necrosis, but it typically involves both femoral head and

**FIGURE 6-19.** Lateral radiograph of the left hip. There is a bump along the superior margin of the left femoral head-neck junction that makes for an aspherical configuration of the femoral head. This is characteristic of Cam-type femoroacetabular impingement.

**FIGURE 6-20.** **A:** Coronal T1 MR arthrogram. There is an intermediate signal intensity subcortical cyst (herniation pit) related to pressure erosion from the incongruent joint (*large arrow*). A labral tear (*short arrow*) and remodeling to the superior acetabulum (*arrowhead*) are well appreciated. **B:** Coronal PD fat suppressed with intra-articular contrast. The subcortical cyst is hyperintense (*large arrow*). The labral tear is better delineated (*short arrow*).

neck and becomes hyperintense on T2-weighted images, suggesting the presence of edema. MRI demonstrates osteoarthritic subchondral sclerosis as low-signal-intensity zones in the subchondral marrow of both the femoral head and acetabulum. MRI also has been found to be very useful for identifying stress or occult fractures. These appear as low-signal-intensity areas containing an oblique or wavy line of still lower signal intensity, representing the actual fracture site. On T2-weighted images, these areas become hyperintense, suggesting that they are edema. MRI also can identify many types of soft-tissue abnormalities about the hip, including synovial cysts, periarthritic bursitis, soft tissue masses and articular abnormalities such as synovial chondromatosis.

Another hip region imaging application of potential interest to physiatrists involves the use of technetium bone scanning to evaluate recently described “thigh splints” caused by exaggerated stride length by short female basic trainees in the unisex-oriented military (34). Seven cases of thigh pain in female recruits at one military base were imaged after administration of technetium-99, with the expectation of finding stress fractures. Instead, the scans showed longitudinal linear accentuation sites in the upper or middle femur that were consistent with periosteal elevation and corresponded with the sites of insertion of one or more of the adductor muscles (Fig. 6-21). The reason these findings occur only in female trainees is explained by a Saunders and colleagues’ classic description of pelvic rotation as the first of their six determinants of gait (35). Because the shorter female recruits had to march with taller males, their stride had to be lengthened to maintain straight lines of march, and exaggerating the normal pelvic rotation lengthens stride. The adductor muscles are important pelvic rotators, and their overuse apparently produced avulsion and elevation of the periosteum adjacent to their femoral insertions.

## Knee

Patients complaining of traumatic or nontraumatic knee pain should undergo plain film radiographic examination with AP and lateral (Lat) knee radiographs. Patients, who complain of anterior knee pain, should undergo an additional axial (Merchant) view to the patella. In elderly patient, where degenerative osteoarthritis is highly prevalent, standing views of the knees should be order. Standing views with the knee flexed can better predict the degree of cartilaginous loss within the posterior medial and lateral knee compartments (36,37).

**FIGURE 6-21.** Thigh splint sites demonstrated by technetium-99 scintigraphy. The accentuation sites (*arrowheads*) correspond to the insertions of the adductor longus and magnus muscles.

**FIGURE 6-22.** Sagittal MR images through a normal peripheral menisci. The anterior and the posterior (*arrow*) horns appear wedge (triangular) in shape.

The use of MRI in the evaluation of osseous and soft-tissue derangements of the knee has increased substantially in recent years. MRI of the knee is the most commonly performed non-neurologic MRI study. At most institutions, it has completely replaced knee arthrography as a diagnostic tool (38).

## MENISCAL INJURIES

All parts of both menisci are well visualized by MRI. Sagittal MR images provide good views of the anterior and posterior horns and a fair view of the body of both menisci. In more central sections, both horns of the menisci appear as wedge-shaped signal voids contrasted on their superior and inferior surfaces by the moderate signal intensity of the hyaline cartilage on the articular surfaces of the femur and tibia. In more peripheral sections, where the images are tangential to the circumference of the menisci, they appear bow tie shaped (Fig. 6-22). Coronal MR images provide the best visualization of the bodies of both menisci.

There are three types of meniscal findings visualized by MRI (16,39,40). One is the presence of small globular or irregular high-signal-intensity foci confined to the interior of the meniscus. This is considered to be an early type of mucoid degeneration. A second type of meniscal MRI finding is the presence of a linear region of increased signal intensity within the meniscus that does not extend to either the femoral or tibial articular surface of the meniscus but may extend to the meniscocapsular junction. Histologically, this represents fragmentation and separation of the fibrocartilage and is considered by many to be an intrameniscal tear. The significance of the globular or linear signals that do not extend to either articular surface of the meniscus is not fully agreed on (41).

Frank meniscal tears are demonstrated by MRI as linear or irregular areas of signal intensity that extend to one or both articular surfaces of the meniscus (Fig. 6-23). The high signal intensity is produced by synovial fluid in the crevices within the meniscus. These meniscal tears can be horizontal, vertical, or complex. Bucket-handle tears are vertical tears where the inner meniscal fragment is displaced toward the intercondylar notch (Fig. 6-23C,D). At times, repeated trauma or chronic degeneration may cause a gross distortion of meniscal shape, and the meniscus may then appear to have a truncated apex or to be grossly small with a free fragment.

Other meniscal abnormalities well visualized by MRI include discoid meniscus, meniscal cysts, and abnormalities involving the postoperative meniscus. In discoid meniscus, typically involving the lateral meniscus, there is a continuous bridge of meniscal tissue between the anterior and the posterior horns in the central part of the joint. Meniscal cysts are usually associated with underlying horizontal meniscal tears through which synovial fluid collects at the meniscocapsular junction (42). They show high signal intensity on T2-weighted images. MRI also can be used to evaluate the postmeniscectomy patient with continuing or recurrent symptomatology (39). It can detect an incompletely excised meniscal tear, retained meniscal fragments, or a tear developing within the residual part of the meniscus. MR arthrography with gadolinium can be helpful to distinguish between retears and old healed tears that might still show increased signal intensity on T2-weighted images (43).

## CRUCIATE LIGAMENT INJURIES

The cruciate ligaments are best visualized by sagittal or oblique sagittal MR images that display the full length of the ligaments (Fig. 6-24A). On straight sagittal images, the slender nature of the anterior cruciate ligament and its oblique course cause a volume-averaging effect that averages fat signal intensity about the ligaments with the normal low signal intensity of the ligament so that the anterior cruciate ligament frequently does not appear as a complete signal void. Furthermore, straight sagittal images typically fail to demonstrate the anterior cruciate ligament's femoral attachment because of its oblique orientation in both sagittal and coronal planes. Oblique sagittal images that parallel the ligament show the full thickness and length of the anterior cruciate ligament without subjecting it to partial volume averaging (44). In the extended position of the knee, which is typically used for MR images, the anterior cruciate ligament is normally taut. The posterior cruciate ligament is a thicker ligament and is therefore well visualized on straight sagittal MR images (Fig. 6-24B). It can be visualized as a signal void structure from its attachment to the posterior tibial intercondylar area to its attachment on the medial femoral condyle. With the knee extended, the posterior cruciate ligament is visualized as thick and posteriorly bowed. It straightens with knee flexion. Axial images can be very helpful to evaluate the femoral insertion of the anterior and the posterior cruciate ligaments.

**FIGURE 6-23.** Meniscal tears. **A:** T1-weighted MRI of a horizontal tear (*arrow*) at the posterior horn of the medial meniscus that extends to its tibial articular surface. **B:** Coronal PD-weighted image of a bucket-handle tear. There is a displaced fragment from the lateral meniscus into the intercondylar fossa (*arrow*). **C:** Sagittal FSE-PD fat suppressed sequence of a double “PCL sign.” The displaced fragment from a bucket handle tear (*arrow*) projects anterior to the PCL. **D:** Sagittal PD fat suppressed sequence through the lateral tibiofemoral joint demonstrates the double delta sign. The displaced anterior horn from a large flap injury is projecting anterior to the posterior horn.

The MRI appearance of an anterior cruciate ligament injury depends on the site and degree of disruption, as well as on the age of the tear. A complete tear may be visualized as a discontinuity of the ligament (Fig. 6-25A–D). In the acute complete tear, the interval between the torn ends of the ligament is often occupied by a mass of intermediate signal intensity on T1-weighted images that appears hyperintense on T2-weighted images (45). At other times, the torn ligament may present as a fusiform or irregular soft-tissue mass of intermediate signal intensity on T1-weighted images that appears hyperintense on T2-weighted images. These fluid masses are usually a combination of edema and hemorrhage, and there may be an associated joint effusion. If the ligament tears from

its femoral attachment, the axial images will show fluid signal between the lateral femoral condyle and the expected ligament insertion. In partial tears there is no complete discontinuity, but the ligament that appears intact on a T1-weighted image may show a hyperintense signal on T2-weighted images, or the ligament may display an interrupted or concave anterior or posterior margin when the knee is extended (42). In chronic anterior cruciate ligament deficiency, there may be a complete absence of the ligament, or there may be only remnants remaining in its usual location. Some secondary signs of anterior cruciate ligament injury may be present. These include a forward shift of the tibia and an anterior bowing or buckling of the posterior cruciate ligament caused by the position of the

**FIGURE 6-24.** Normal cruciate ligaments. **A:** An oblique sagittal MRI parallel to the anterior cruciate ligament demonstrates excellent visualization of all borders and attachments of the anterior cruciate ligament (*arrow*). **B:** A T2-weighted MRI of the posterior cruciate ligament (*arrow*), which is normally posteriorly bowed when the knee is extended.

knee within the coil, which duplicates the knee position of an anterior drawer or Lachman test (39).

On T1-weighted MR images, partial tears of the posterior cruciate ligament typically appear as foci of increased signal intensity within the normal black signal void of the ligament. These appear hyperintense on T2-weighted images. With complete tears, a frank discontinuity is visualized with an intervening fluid mass that becomes hyperintense on T2-weighted images (Fig. 6-26). The gap between the ends of a completely torn posterior cruciate ligament can be exaggerated by imaging the knee in flexion, which tenses the posterior cruciate ligament.

## COLLATERAL LIGAMENT INJURIES

The collateral ligaments are best visualized by coronal MR images (Fig. 6-27). The medial collateral ligament appears as a narrow low-signal-intensity band extending from the medial epicondyle of the femur to an attachment on the anteromedial aspect of the tibia 5 to 6 cm below the joint line. It is overlaid at its tibial attachment by the tendons of the pes anserinus, which are separated from it by an intervening anserine bursa that is not visualized unless it is inflamed. Deep to the tibial collateral ligament, the medial capsular ligament, sometimes called the *deep portion of the tibial collateral ligament*, has femoral and tibial attachments close to the joint interval and deep attachments to the medial meniscus, referred to as the *menisiofemoral and meniscotibial* or *coronary ligaments*. Valgus and rotary stresses can injure the medial capsular ligament or the tibial collateral ligament, usually in that order (39). In a complete rupture (i.e., grade III injury), MRI can show discontinuity, serpentine ligamentous borders, and edema within adjacent

connective tissues. In a partial tear (i.e., grade II injury) or in the case of microtears confined to the ligament substance (i.e., grade I injury), the ligament may show no discontinuity, but the overlying subcutaneous fat typically demonstrates edema and hemorrhage, which is indicated by moderate signal intensity on T1-weighted images and high signal intensity on T2-weighted images. Injury to the tibial collateral ligament is commonly associated with injuries to the anterior cruciate ligament and medial meniscus.

The lateral collateral complex commonly refers to the lateral supporting structures of the knee, whose main components are the iliotibial tract, the lateral collateral ligament, the long head of the biceps femoris, and the popliteofibular ligament. These structures are best seen on axial and coronal MR images as a low-signal-intensity band extending somewhat obliquely from the lateral femoral epicondyle to the fibular head. The lateral collateral ligament is usually injured by varus and rotary stresses to the knee, although its frequency of injury is less than that of the tibial collateral ligament. The MRI findings of the injured fibular collateral ligament are similar to those for the tibial collateral ligament.

## OTHER KNEE ABNORMALITIES

Patellar tendinitis (jumper's knee) is demonstrated by MRI as an area of edema within the patellar ligament (i.e., tendon) at its patellar (Fig. 6-28) or tibial tuberosity attachment. There is also associated edema in the adjacent subcutaneous fat or the infrapatellar fat pad.

Ischemic necrosis about the knee most commonly involves the weight-bearing surface of the medial femoral condyle, and its MRI findings are as described for the hip.

**FIGURE 6-25.** Acute ACL injury; spectrum of findings. **A:** Sagittal PD and **B:** Sagittal PD fat suppressed sequences. The *arrow* demonstrates the torn ACL resting against the tibial spine. There is diffuse marrow edema with increased signal intensity on the T2-weighted sequence. **C:** Axial T2-weighted fat suppressed sequence. The *long arrow* is pointing to the ACL fibers. There is edema anterior to the ACL (*short arrow*) within the intercondylar fossa. The *arrowheads* demarcate an area of marrow edema within the lateral femoral condyle. **D:** There is bone marrow edema within the posterior tibial plateau (*long arrow*) and the anterior femoral condyle (*short arrow*), typical contusion pattern in ACL injuries. There is a small radial tear to the free inner margin of the lateral meniscus (*arrowhead*) secondary to the compression injury.

Osteochondritis dissecans occurs mainly in adolescents and involves a partial or total separation of a segment of articular cartilage and subchondral bone from the underlying bone (39). It commonly involves the intercondylar portion of the medial femoral condyle articular surface. It is visualized on T1-weighted MR images as a low-signal-intensity region in the

subchondral bone with or without disruption of the overlying articular cartilage (Fig. 6-29A,B). If the involved osteochondral segment becomes completely separated from the underlying bone, it becomes an intra-articular loose body. The role of MRI in osteochondritis dissecans is mainly to determine the stability of the fragment, because the treatment hinges on that.

**FIGURE 6-26.** Sagittal T1-weighted image of a chronic PCL tear. The arrow points to the thickened posterior cruciate ligament. Intermediate signal intensity is replacing the normal hypointensity of the ligament.

**FIGURE 6-28.** Sagittal T2-weighted fat suppressed image of patellar tendinitis. The arrow points to the increased signal intensity within the proximal tendon fibers and the adjacent infrapatellar fat pad.

Chondromalacia patella can be diagnosed and graded noninvasively by MRI (40). In stage I, the posterior patellar articular cartilage demonstrates local areas of cartilage swelling with decreased signal intensity on both T1- and T2-weighted images. Stage II is characterized by irregularity of the patellar articular cartilage with areas of thinning. Stage III demonstrates complete absence of the articular cartilage with synovial fluid extending through this cartilaginous ulcer to the subchondral bone (Fig. 6-30).

Popliteal (i.e., Baker's) cysts and other synovial cysts about the knee appear hyperintense on T2-weighted images (Fig. 6-31A–D). They can be visualized on axial, sagittal, or coronal images. Popliteal cysts are usually an enlargement of the semimembranosus-gastrocnemius bursa, which is located between the tendon of insertion of the semimembranosus and the tendon of origin of the medial head of the gastrocnemius. Popliteal cysts may communicate with the knee joint and therefore may be caused by chronic knee joint pathology that

**FIGURE 6-27.** Tibial collateral ligament tear (MCL). **A:** Coronal T2-weighted fat suppressed sequences of grade I injury. There is edema (short arrows) overlying the intact fibers of the MCL (long arrow). **B:** Normal MCL (arrow).

**FIGURE 6-29.** Osteochondral lesion (previously osteochondritis dissecans). T2-weighted fat suppressed (**A**) and PD (**B**) sequences. **A:** There is a hyperintense T2 signal at the interface of the OC lesion and the adjacent cortex compatible with an unstable fragment. **B:** The lesion is well demarcated by a hypointense rim (*short arrows*).

produces effusion. A previously undescribed bursa is now known to be consistently present between the tibial collateral ligament and a major slip of the semimembranosus tendon that extends beneath it, and may serve to clarify many cases of previously unexplained medial knee pain (46). Inflammation of this bursa is well demonstrated by MRI (Fig. 6-32A,B).

### Ankle

MRI is valuable as a screening modality for assessing a variety of painful ankle disorders (47–51).

**FIGURE 6-30.** Grade IV chondromalacia. Sagittal PD sequence with grade IV chondromalacia. There is a full thickness defect (*arrow*) with subchondral bone sclerosis and early subchondral cyst formation within the proximal patella.

## LIGAMENT INJURIES

Previously, arthrography and tenography were the primary means of imaging ankle ligament injuries. They had the limitations of being invasive, providing only an indirect depiction of ankle ligament disruption, and yielding potentially false-negative results. MRI provides a noninvasive means of directly imaging all the ligaments in the vicinity of the ankle as well as all the other osseous and soft tissues.

Axial MR images provide good visualization of the tibiofibular ligaments of the tibiofibular mortise. All the lateral collateral ligaments of the ankle have an oblique orientation, and to image these ligaments in full length, either an oblique imaging plane that parallels their length must be chosen or the foot must be placed in sufficient dorsiflexion or plantar flexion to bring the ligaments into one of the standard imaging planes. With the imaging plane parallel to the anterior talofibular ligament, it is displayed as a low-signal-intensity band extending anteromedially from the lateral malleolus to gain attachment to the talus just anterior to its fibular articular surface (Fig. 6-33A) (50). The calcaneofibular ligament is visualized as a low-signal-intensity structure extending from the lateral malleolus to the calcaneus, with the peroneus longus and brevis tendons situated superficial to its fibular end (Fig. 6-33B). The posterior talofibular ligament is visualized as a wide low-signal-intensity structure extending from the deep surface of the lateral malleolus to a broad attachment on the talus from its fibular articular surface to its posterior process (Fig. 6-33C).

MRI of ankle ligament injuries offers promise for the noninvasive evaluation of the site and severity of both acute ankle ligament injuries and chronic ankle instability (51).

The mechanism of injury of the lateral collateral ligaments typically involves plantar flexion and inversion, and they are usually injured in a predictable sequence from anterior to posterior. The anterior talofibular ligament is the most commonly

**FIGURE 6-31.** Baker's cyst. **A:** A T1-weighted axial MRI demonstrates a hypointense Baker's cyst (*arrowheads*) in the interval between the semimembranosus (SM) and the medial head of the gastrocnemius (MG). T1-weighted (**B**) and T2-weighted (**C**) sagittal MR images through Baker's cyst (*arrowheads*). Note that the hypointense fluid in the cyst in the T1-weighted image becomes hyperintense on the T2-weighted image. **D:** A coronal T1-weighted image locates the cyst between the SM and the MG.

injured, followed in sequence by injury to the calcaneofibular and posterior talofibular ligaments. The major MRI finding in a complete rupture (i.e., grade III sprain) of the anterior talofibular ligament is a complete discontinuity of the ligament visualized at all imaging levels (Fig. 6-34A,B). This is accompanied by periarticular edema or hemorrhage and joint effusion because this ligament is a thickening of the ankle joint

capsule. The edema and effusion are visualized with moderate signal intensity on T1-weighted MR images and hyperintensity on T2-weighted images. A partial tear (i.e., grade II sprain) of the anterior talofibular ligament is visualized on MRI as a discontinuity of the upper part of the ligament, with the lower portion remaining intact. Again, there is periarticular edema, hemorrhage, and joint effusion. Grade II sprains of the

**FIGURE 6-32.** Axial (**A**) and coronal (**B**) T2-weighted PD fat suppressed sequences. **A:** There is minimal fluid anterior to the semimembranosus (*long arrow*). **B:** The fluid is deep to the semitendinosus (St) and superficial to the meniscocapsular junction of the medial meniscus (*long arrow* in B).

calcaneofibular ligament may appear as a longitudinal splitting or waviness of the ligament with fluid accumulation within the tendon sheath of the overlying peroneal tendons (Fig. 6-35).

In contrast to the three discrete lateral collateral ligaments, the medial collateral or deltoid ligament is a continuous ligamentous sheet with an apical attachment to the tibial

**FIGURE 6-33.** T1-weighted images of the normal lateral collateral ligaments of the ankle. **A:** The anterior talofibular ligament (ATAF) extends from the fibular malleolus to the neck of the talus. **B:** The calcaneofibular ligament (CFL) attaches to the calcaneus and is deep to the peroneus tendons. **C:** The strong talofibular ligament (between *arrowheads*).

**FIGURE 6-34.** Complete rupture of the anterior talofibular ligament. Axial T1-weighted (**A**) and T2-weighted fat suppressed sequences (**B**). There is discontinuity to the ligament fibers (*arrows*) and associated soft tissue swelling (*arrowhead* in B).

**FIGURE 6-35.** Partial tear to the calcaneofibular ligament. There is thickening and increased signal within the ligament fibers (*long arrow*) and edema within the soft tissues between the ligament and the calcaneus.

malleolus, and a broad base attaching below to the navicular, talar neck, spring ligament, sustentaculum tali of the calcaneus, and posterior talus. The posterior tibiotalar part of the deltoid ligament is its thickest and strongest (52). The deltoid ligament can be visualized by either axial or coronal MRI. Axial images allow simultaneous visualization of all parts of the deltoid ligament, the overlying flexor retinaculum, and the walls and contents of the tarsal tunnel (Fig. 6-36A). The contents of the four compartments under the flexor retinaculum include, from anterior to posterior, the tibialis posterior tendon, flexor digitorum longus tendon, posterior tibial artery, tibial nerve, and flexor hallucis longus tendon. Coronal MR images through the deltoid ligament display the proximal and distal attachments of each part of the deltoid ligament (Fig. 6-36B).

MRI has the potential to visualize even grade I sprains, which are microtears confined to the interior of the ligament. The minute foci of edema and hemorrhage accompanying such tears become hyperintense on T2-weighted images. Findings compatible with such grade I tears have been identified in the posterior tibiotalar portion of the deltoid ligament. They are frequently accompanied by fluid within the tendon sheath of the overlying tibialis posterior.

In chronic ankle instability, MR images show thinned, lengthened, wavy ligaments in some locations and thickened, scarred ligaments in others.

**FIGURE 6-36.** Normal tibial collateral ligament (i.e., deltoid ligament) and contents of the tarsal tunnel. **A:** Axial T1-weighted image demonstrates the deltoid ligament (DL), flexor retinacula (FR), tibialis posterior (TP), flexor digitorum longus (FDL), posterior tibialis artery and vein (PTA/V), posterior tibialis nerve (PTN) and the flexor hallucis longus (FHL). **B:** Coronal T2-weighted fat suppressed image demonstrating the superficial and deep fibers of the deltoid ligament.

## OTHER ANKLE ABNORMALITIES

Technetium-99 scintigraphy has been valuable for detecting stress fractures of metatarsal and tarsal bones, and CT has high accuracy for detecting osteochondral fracture. In foot pain of undetermined etiology, however, MRI is an excellent screening modality because it permits direct evaluation of all osseous and soft-tissue structures.

MRI is superior to any other modality in displaying tendon pathology (47,48). In tenosynovitis, MRI detects fluid within the tendon sheath as having moderate signal intensity on T1-weighted images and as hyperintense on T2-weighted images. Tendinosis is commonly observed in the Achilles, tibialis posterior, flexor hallucis longus, tibialis anterior, and peroneal tendons (Fig. 6-37). Tendinosis is visualized as a focal or diffuse thickening of the tendon that may show areas of

**FIGURE 6-37.** **A:** Axial T1-weighted image at the level of the talar dome. There is thickening and splitting to the fibers of the peroneus brevis (*short arrows*). Note normal signal and configuration to the peroneus longus (PL). **B:** Axial PD fat suppressed sequence. The split fibers of the peroneus brevis are better depicted (*arrowheads*). There is an effusion within the tendon sheath (*short arrow*).

**FIGURE 6-38.** **A:** Sagittal T1-weighted image of the hindfoot. There is thickening and increased signal (*short arrow*) within the proximal fibers of the plantar fascia (PF). TT tarsal tunnel; ST, sustentaculum talus. **B:** Coronal T2-weighted fat suppressed sequence. There is asymmetric thickening and increased signal to the medial bundle of the plantar fascia (MB). Edema extends into the adjacent fat (*arrowhead*). Note normal thickness and signal to the lateral bundle (LB).

increased signal intensity on T2-weighted images. Plantar fasciitis shows similar changes within the plantar aponeurosis (Fig. 6-38). With a complete tendon rupture, axial MR images show absence of the tendon and its replacement by edema. Sagittal and coronal MR images display the site of discontinuity, with edema occupying the gap and surrounding the torn ends of the tendon.

Stress fractures of the tarsal or metatarsal bones appear on MRI as linear areas of decreased marrow signal intensity. There are adjacent areas of marrow edema that are hypointense relative to marrow fat on T1-weighted images and hyperintense on T2-weighted images (47). By MRI, osteochondral fractures (e.g., of the talar dome) have an appearance similar to that of osteochondritis dissecans of the knee. The primary task of MRI is to determine the stability of the fragment by demonstrating the integrity of the articular cartilage and the absence of fluid between the osteochondral fragment and the parent bone. Synovial cysts of intertarsal joint origin demonstrate moderate signal intensity on T1-weighted images and high signal intensity on T2-weighted images.

## COMMON ARTHRITIDES

The usual mode for diagnosing the arthritides is plain film radiography. However, MRI is a very useful tool particularly for the assessment of acute inflammatory arthritides. Only the findings of the more common arthropathies will be described.

### Osteoarthritis

Osteoarthritis or degenerative joint disease (DJD) is an asymmetric, usually bilateral mechanical degenerative process that involves joints significantly involved in weight bearing, such

as the hip, knee, and spine, and those involved in frequent repetitive mechanical trauma, such as the distal interphalangeal joints of the fingers, trapezium–first metacarpal joint, trapezium–scaphoid joint, and metatarsophalangeal joint of the great toe. It is the most common arthritis, and it is estimated that 80% of the population with more than 50 years will show radiographic evidence of osteoarthritis. The most common radiographic findings include the following:

- Nonuniform loss of joint space caused by cartilage degeneration in high load areas (e.g., the superior aspect of the hip and medial knee).
- Sclerosis of the subchondral bone.
- Osteophyte formation at the margins of the articular surfaces.
- Cystlike rarefactions in the subchondral bone that may collapse to produce marked joint deformities.
- Adjacent soft-tissue swelling (e.g., that which occurs with Heberden's nodes of the distal interphalangeal joints of the fingers) (Fig. 6-39) (53).

### Rheumatoid Arthritis

Rheumatoid arthritis is a connective tissue disorder of unknown etiology that can affect any synovial joint in the body. It is a bilaterally symmetric inflammatory degenerative disease that involves the following joints in order of decreasing frequency:

- Small joints of the hands and feet, with the exception of the distal interphalangeal joints
- Knees
- Hips
- Cervical spine
- Shoulders
- Elbows

**FIGURE 6-39.** Frontal projection of both hands demonstrates joint space narrowing, marginal osteophytosis, subchondral bone sclerosis involving the distal interphalangeal joints and the triscaphae joints (*short arrow*) of the hands and wrist. In this patient, there are erosions on the right second DIP and left third DIP joints (*long arrow*) that suggest erosive OA.

The major radiographic findings include the following:

Symmetric periarticular *soft-tissue swelling*

Juxta-articular *osteoporosis* proceeding to diffuse osteoporosis

*Erosions* of the intracapsular portions of the articulating bones not covered by cartilage, which can proceed to severe subchondral bone erosion

Uniform joint space narrowing

Synovial cysts (e.g., Baker's cysts behind the knee)

Subluxations (e.g., boutonniere or swan-neck deformities of the fingers, and palmar and ulnar subluxation of the proximal phalanges on the metacarpal heads) (Fig. 6-40A,B) (54)

**FIGURE 6-40.** Frontal projections of both hands. There is extensive erosive disease within the wrist joints bilaterally, ulnar subluxations to the 2nd, 3rd MCP and to the 4th PIP and radial subluxation to the 5th PIP on the left.

### Seronegative Spondyloarthropathies

These disorders are all linked to the human leukocyte antigen (HLA)-B27 histocompatibility antigen. These groups of diseases include ankylosing spondylitis, inflammatory bowel disease, psoriatic arthritis, and reactive arthritis. They are characterized by osseous ankylosis, proliferative new bone formation (syndesmophytes), and predominantly axial (spinal and sacroiliac) involvement.

### Gout

Gout is a metabolic disorder that most commonly involves the feet, especially the first metatarsophalangeal joint, as well as the

**FIGURE 6-41.** Gout arthritis affecting the 1st MTP joint. There are large periarticular bone erosions with overhanging edges (*arrow*) and significant soft tissue swelling.

ankles, knees, hands, and elbows in asymmetric fashion. It is produced by a deposition of monosodium urate crystals in tissues with a poor blood supply, such as cartilage, tendon sheaths, and bursae. The radiographic features of gout typically do not appear until after 4 to 6 years of episodic arthritis. Radiographic features characteristic of gout include the following:

- Tophi or periarticular soft-tissue nodules/masses created by the deposition of urate crystals that may contain calcium.
- Tophi-induced periarticular or intra-articular bone erosion.
- Prominent cortical edges overhanging the tophi and well-defined bone erosions (with sclerotic margins) (Fig. 6-41) (54).

Random distribution, without marked osteoporosis.

### Calcium Pyrophosphate Dehydrate Deposition Disease

It is also known as *pseudogout* and has the classic triad of pain, cartilage calcification, and joint destruction. Chondrocalcinosis at the knee, wrist, or symphysis pubis is virtually diagnostic of calcium pyrophosphate dehydrate deposition disease (CPPD) (Fig. 6-42).

### Diffuse Idiopathic Skeletal Hyperostosis

Diffuse idiopathic skeletal hyperostosis (DISH) is not really an arthropathy because it spares synovium, articular cartilage, and articular osseous surfaces. It is a fairly common ossification process involving ligamentous and tendinous attachments to bones and occurs in 12% of the elderly (55). It most commonly affects the thoracic spine but also may involve the

**FIGURE 6-42.** Chondrocalcinosis. Frontal radiograph of the right knee. Calcifications (*arrows*) are present within the medial and lateral tibiofemoral joint along the expected location of the meniscus.

pelvis, foot, knee, and elbow. It can involve ossification of all the ligaments surrounding the vertebral bodies, particularly the anterior longitudinal ligament. Ossification of the posterior longitudinal ligament (OPLL) can also be seen. This is reported to be more common in orientals and can be responsible for significant spinal canal stenosis. By definition, DISH must involve a flowing ossification of at least four contiguous vertebral bodies (Fig. 6-43A,B). There must be normal disc spaces and facet joints, without joint sclerosis.

## SPINE AND SPINAL CORD IMAGING

It is clear, after multiple research studies to assess the usefulness of imaging in low back pain, that uncomplicated acute low back pain is a benign, self-limited condition that does not warrant any imaging studies. The vast majority of patients are back to their usual activities within 30 days. Radiographic evaluation of the lumbar spine includes frontal and lateral radiographs. These are indicated in the evaluation of back pain and weight loss, after mild trauma in patients older than 50 y/o, in patients with unexplained fever, immunosuppression, history of cancer, prolonged use of steroids and focal neurologic, or disabling symptoms. Oblique views are useful for the assessment of defects to the pars interarticularis when suspecting spondylolysis and for the evaluation of the nerve root foramina. The relative radiation dose level for a routine

**FIGURE 6-43.** Diffuse idiopathic skeletal hyperostosis. Frontal (**A**) and lateral (**B**) radiographs of the lower thoracic spine. There are flowing ossifications (*arrowheads*) of the paraspinal ligaments bridging more than four segments of the spine. Note relative preservation of the intervertebral disc spaces.

radiographic examination of the lumbar spine is between 1 and 10 mSv (56). Although plain radiographs remain valuable for detecting many types of spine fractures and degenerative changes, the high resolution of osseous and soft-tissue structures provided by CT and MRI has made these modalities invaluable for the diagnosis of degenerative, traumatic, neoplastic, and infectious diseases of the spinal column and spinal cord.

### Degenerative Spine Disorders

CT and MRI provide complementary information about degenerative diseases of the spine. MRI is often the modality of choice in assessing degenerative changes within the spine due to its superior soft-tissue contrast. CT has superior spatial resolution and provides better conspicuity of osseous and calcified structures. The advent of MDCT technology allows for superb reconstruction in the sagittal and the coronal planes that allows for better depiction of pathologic processes and hardware evaluation in the post-operative spine (57). MRI permits noninvasive visualization of the spinal cord and subarachnoid space within the spinal canal and the nerve roots within the neural foramina. Discrimination of these structures by CT requires injection of intrathecal contrast agents. MRI has a superior ability to evaluate intramedullary abnormalities. It also offers direct multiplanar imaging capabilities.

Axial CT images of the normal cervical and lumbar spine (Figs. 6-44 and 6-45) provide good visualization of all osseous elements, including the facet joints. In the cervical spine, the

uncovertebral joints (i.e., Luschka) are well depicted with coronal reformatted and sagittal oblique images. Sagittal oblique images through the lumbar spine provide excellent anatomical reconstruction of the pars interarticularis for the assessment of spondylolysis. Soft-tissue windows typically permit visualization of the moderate radiodensity of the soft-tissue structures, such as the intervertebral disc, ligamentum flavum, and thecal sac. Sagittal images provide assessment of anatomical alignment, intersegmental instability and allows for adequate evaluation of foraminal stenosis. The epidural fat contains the internal vertebral venous plexus, which can be enhanced by a circulating bolus of contrast material to improve visualization of soft-tissue encroachments into the spinal canal, such as herniated discs. Introduction of contrast material into the subarachnoid space (i.e., CT myelography) delimits the contained spinal cord and the nerve roots (Fig. 6-46).

The introduction of MDCT technology allows for the acquisitions of multiple thin cut images in the axial plane that can be reconstructed in the sagittal and the coronal planes. The high spatial resolution of the acquired data allows for near-perfect isometric reconstruction in different planes. In addition, computer-generated volume rendering images provide superb 3D images of the spine (Fig. 6-47A–C).

Sagittal T1-weighted MR images of the cervical, thoracic, or lumbar spine provide excellent noninvasive survey to evaluate patients with suspected regional spinal pathology. Midsagittal T1-weighted images display the high-signal-intensity marrow of the vertebrae bordered by low-signal-intensity cortical

**FIGURE 6-44.** MDCT of the normal cervical spine. **A:** Bone window CT of the cervical spine in the axial plane at the level of C5-6 displays normal facet joints (*short arrow*) and Luschka joints (*long arrow*). **B:** Coronal multiplanar reformatted images (MPR) through the level of the uncoversal joints (*arrow*). **C:** Midplane sagittal reconstructed images of the cervical spine shows mild reverse of the normal lordosis that could be secondary to spasm or associated to positioning. Note adequate alignment and no intersegmental subluxations. **D:** Sagittal oblique MPR demonstrates the nerve root foramina, uncoversal joints, and facet joints.

bone. Structures displaying very low signal intensity include the peripheral part of the annulus fibrosus of the intervertebral disc, all ligaments, the dura, and the cerebrospinal fluid (CSF), and these are usually indistinguishable from each other (Fig. 6-48A–C). The nucleus pulposus, and probably the inner portion of the annulus fibrosus, shows moderate signal intensity. The spinal cord and the nerve roots display moderate signal intensity, which is well contrasted against the low-signal-intensity CSF. Collections of epidural fat, which are largest at lumbar levels, produce high signal intensity on T1- and T2-weighted images. On T2-weighted MR images, CSF and the normal well-hydrated nucleus pulposus assume high signal intensity.

### Degenerative Disc Disease

The intervertebral disc space is a cartilaginous joint with a central nucleus pulposus surrounded by an annulus fibrosus. Degenerative change in the nucleus pulposus is termed *intervertebral osteochondrosis* (Fig. 6-49A,B). Early signs of disc disease may include loss of fluid signal within the nucleus pulposus (dehydration), which results in decreased signal within the central portion of the disc on T2-weighted images, and blurring of the transition between the nucleus pulposus and the annulus fibrosus. This is followed later by narrowing of the intervertebral disc, which sometimes results in vertebral body end-plate degenerative changes. These end-plate changes

**FIGURE 6-45.** Normal lumbar spine CT. **A:** Axial soft-tissue window CT of L5 demonstrating thecal sac (T), L5 nerve root (NR) within the lateral recess, epidural fat (E), and ligamentum flavum (LF). **B:** Bone windows axial through the same level demonstrate the sclerotic margins of the facet joint and the right sacroiliac joint. **C:** Midplane sagittal reconstruction (MPR image). Normal homogeneous trabecular pattern. Note intervertebral space distance and anatomical alignment of the anterior and posterior surface to the vertebral bodies. **D:** The density of the nucleus pulposus (NP) and annulus fibrosus (AF) can be appreciated. Note decreased attenuation to the CSF in the thecal sac. **E:** Oblique reconstruction through the posterior elements demonstrating the normal facet joints and pars interarticularis.

**FIGURE 6-46.** Metrizamide CT myelogram at L1 level delimiting the spinal cord (SC), nerve roots (NR) arising from the cord, and the contrast-enhanced CSF.

are referred to as *Modic changes* (58). Modic type I changes are characterized by signal of edema, that is decreased signal on T1-weighted images and increased signal on T2-weighted images. Type II changes (Fig. 6-50A,B) follow the signal characteristic of fat, with intermediate to increased signal on T1-weighted images and increased signal on T2-weighted images. This is the most common type of reactive end-plate changes appreciated on degenerative osteochondrosis. Type III changes represent osseous sclerosis, characterized by decreased signal on both the T1- and the T2-weighted images.

When the disc becomes degenerated, it may undergo tearing of the annulus fibrosus collagen bundles, which is often a precursor to herniation of the nucleus pulposus, particularly at the posterolateral aspect of the disc. Protrusion is herniation of the nucleus pulposus that is contained by the annulus. In the axial plane, it usually demonstrates a base broader than the height against the parent disc (59). Extrusion is defined as a herniation of the nucleus pulposus beyond the fibers of the

Facet joint (FJ), pars interarticularis (PI), and pedicle (P).

**FIGURE 6-48.** MRI of the normal spine and spinal cord. **A:** A T2-weighted axial MRI at the L5-S1 disk level shows the thecal sac (T) as an area of high signal intensity, the nerve roots (S1, S2) within the posterior thecal sac are of low signal intensity. Note the ligamentum flavum (LF), and fluid within the facet joints (FJ) with high-signal-intensity fluid. **B:** T1-weighted midsagittal MRI of the lumbosacral spine displays the nucleus pulposus (NP) of the intervertebral discs, spinal cord (SC), conus medullaris (CM), and nerve roots of the cauda equina (CE) as areas of moderate signal intensity. Cerebrospinal fluid (CSF) is of low signal intensity, and epidural fat (E) is hyperintense. **C:** T2-weighted midsagittal MRI of the lumbosacral spine demonstrates the increased intensity of the nucleus pulposus (NP) and CSF.

peripheral annulus. In the axial plane, it can demonstrate a narrower base in relationship to the height of the herniation. A sequestered or free fragment is an extruded disc without contiguity to the parent disc. The majority of disc herniation are central or paracentral (subarticular) in location.

The loss of the load-diffusing function of the normal disc also causes facet joint osteoarthritis and marginal osteophytosis of the vertebral body ends (spondylosis deformans) by virtue of the increased loads these joints must bear.

### Cervical Disc Herniation

Disc herniation is typically preceded by degenerative changes in the mucopolysaccharides of the nucleus pulposus, which produce fibrillation of the collagen (60). This eventually causes dehydration and loss of disc volume. As a result, the nucleus pulposus no longer serves as a normal load-dispersing mechanism, and excessive stress is borne by the annulus fibrosus. This produces annular fissuring and tears that can culminate in herniation of the nucleus pulposus. The loss of the load-diffusing function of the normal disc also causes facet

joint degeneration and marginal osteophytosis of the vertebral body ends by virtue of the increased loads these joints must bear.

Cervical disc herniation occurs with less frequency than lumbar disc herniation. About 90% of cervical disc herniations occur, in order of decreasing frequency, at C5-6, C6-7, and C4-5 (61,62). On CT examination, a herniated cervical disc appears as a dense soft-tissue mass protruding from the disc space centrally or paracentrally into the spinal canal or posterolaterally into the neural foramen (Fig. 6-51).

On T1-weighted MR images, the herniated cervical disc appears as a posterior extension of the moderate signal intensity of the disc into the low-signal-intensity region of the thecal sac (Fig. 6-52A,B). Because the spinal cord appears as a relatively high-signal-intensity structure outlined by the low-signal-intensity CSF, the relationship of the herniated disc to the spinal cord can be visualized directly by MRI. On T2-weighted MR images, the degenerated disc appears as a narrowed disc interval. The disc herniation appears as a moderate- to low-signal-intensity impingement on the now high-signal-intensity

**FIGURE 6-49.** **A:** Sagittal T2WI of the lumbar spine demonstrating different stages of intervertebral osteochondrosis. Normal disk (ND) demonstrates increased signal to the nucleus pulposus and normal height. With early degeneration (ED), the nucleus pulposus loses signal in part related to the decreased water content of the intervertebral disc but preserves the intervertebral height. With advanced degeneration (AD), there is near complete loss to the normal signal of the intervertebral disk and early traction osteophyte formation (TO). Note herniated disk (DH) at the L5-S1 segment. **B:** Advanced degenerative osteochondrosis on a different patient. There is loss of the intervertebral disk height, Schmorl's node formation (SN) representing end-plate herniation and moderate traction osteophyte formation (arrow).

CSF. The posterior margin of the herniated disc may have a very-low-signal-intensity margin interfacing with the CSF. This may be a posterior longitudinal ligament elevated by the herniated disc, or it may be fragments of the posterior part of the annulus fibrosus (61). T2-weighted images also permit evaluation of the relationship of the herniated disc to the spinal cord

to determine its probability of causing a patient's myelopathic findings (Fig. 6-53A,B). It is sometimes difficult to differentiate lateral herniations of the disc into the neural foramen from osteophytic encroachments by MRI because they may both demonstrate low signal intensity. In these circumstances, CT provides good differentiation between bone and soft-tissue density.

**FIGURE 6-50.** Sagittal T1- (**A**) and T2- (**B**) weighted images with degenerative osteochondrosis of the cervical spine. There is decreased T2 signal to most intervertebral discs, decreased disc height throughout, annular bulge, and traction osteophytosis. Note increased signal to the inferior end plate of C5 both on the T1- and T2-weighted images (arrows) characteristic of Modic type II changes.

**FIGURE 6-51.** CT evaluation of a herniated C5-6 nucleus pulposus. An axial CT myelogram shows a radiodense protrusion of the C5-6 disc (arrow) that distorts the left anterior aspect of both the thecal sac and the spinal cord.

### Cervical Spinal Stenosis and Foraminal Stenosis

Cervical spinal stenosis can be congenital or acquired. In the less common congenital stenosis, a small spinal canal is produced by short pedicles and thick laminae (62). It commonly remains asymptomatic until degenerative changes are superimposed on the congenital stenosis later in life.

Acquired stenosis can be produced by a host of hypertrophic degenerative changes often collectively referred to as *cervical spondylosis*. These include osteophytic lipping of the posterior margins of the vertebral body ends bordering the disc,

hypertrophic degenerative changes involving Luschka's joints or the facet joints, buckling or hypertrophy of the ligamenta flava, and OPLL. All these structures border the spinal canal; therefore, hypertrophic degenerative changes can produce spinal canal stenosis. Because Luschka's joints, the facet joints, and the ligamenta flava also border the neural foramen, their involvement by degenerative processes can produce foraminal stenosis.

Although hypertrophic degenerative changes of any of the structures bordering the spinal canal or neural foramen can occur in isolation, they are commonly precipitated by intervertebral disc degeneration. As the disc degenerates and loses its normal load-dispersing ability, loads tend to become concentrated on the vertebral body margin toward which the spine is bent. This excessive loading can produce marginal osteophytes around the entire circumference of the vertebral body end plates. Those osteophytes developing on the posterior margin can encroach on the spinal canal to produce spinal stenosis (Fig. 6-54A,B). Luschka (i.e., uncovertebral) joints are situated between the uncinate processes that protrude from the lateral or posterolateral margins of the upper surface of the vertebral bodies and a reciprocal convexity on the lateral aspect of the inferior surface of the next higher vertebral body. Recent evidence indicates that they are not true joints (63). Rather, they are degenerative clefts within the lateral part of the intervertebral disc that begin in the second decade of life. The increased loading of Luschka joints produced by these degenerative changes produces bony spurs that can extend posteriorly into the lateral part of the spinal canal or posterolaterally into the neural foramen (Fig. 6-55A–C).

Disc degeneration is accompanied by dehydration and loss of disc height, with decreased space between vertebral bodies resulting in increased facet joint loads. The resultant

**FIGURE 6-52.** **A:** T2\*-weighted axial MRI of the cervical spine shows a left posterolateral herniated C6-7 nucleus pulposus (between arrow) indenting the thecal sac (arrowhead) and extending into the ostium of the ipsilateral nerve root foramina. **B:** A T2-weighted left parasagittal MRI shows the disc fragment (arrow) impinging upon the intermediate-signal-intensity thecal sac (arrowheads) and low-signal-intensity posterior longitudinal ligament.

**FIGURE 6-53.** **A:** Axial T2-weighted image at the C4-5 level demonstrates a bilobed protrusion contained in the midline by the posterior longitudinal ligament. Note complete obliteration of the normal CSF signal anterior to the cord, posterior displacement, and compression of the cord. **B:** The herniated disc elevates the posterior longitudinal ligament, compresses the cervical cord, which demonstrates increased signal intensity as a sign of myelopathy.

facet joint degeneration involves cartilage erosion with joint space narrowing, subchondral bone sclerosis, and osteophyte formation. The osteophytes may encroach on the spinal canal or the neural foramen.

Loss of disc height results in decrease of the laminae interspace, which causes the ligamentum flavum to buckle and bulge into the spinal canal, contributing to the spinal stenosis. Because the ligamentum flavum continues laterally into the facet joint capsule, buckling of this part of the ligamentum flavum can cause foraminal stenosis.

OPLL occurs more commonly at cervical than at other vertebral levels. It is best visualized via CT, where it appears as an ossification extending over several vertebral levels, separated from the posterior margin of the vertebral bodies by a thin radiolucent interval (Fig. 6-56A,B).

When any of these potential causes of cervical stenosis sufficiently narrow the spinal canal, cord compression can produce myelopathic signs and symptoms. Spinal stenosis most frequently narrows the AP dimension of the spinal canal. Although the cross-sectional area of the spinal canal is smallest

**FIGURE 6-54.** **(A)** Midplane sagittal and **(B)** right parasagittal T2-weighted images in a patient with congenital stenosis and superimposed degenerative spondylosis with central canal narrowing and cord compression. There is increased AP dimension to the C4, C5, and C6 vertebral bodies. Annular bulge and hypertrophy to the supporting ligamentous structures is responsible for compression to the cord. There is linear increased signal to the cord on the T2-weighted image (arrow) compatible with early myelopathy.

**FIGURE 6-55.** Hypertrophic Luschka joints with associated bilateral foraminal stenosis. **A:** Axial image at the C5-6 segment shows the hypertrophic changes to the uncoversbral joints (*arrow*) and associated foraminal stenosis. **B:** Coronal and **C:** sagittal oblique MPR images demonstrates to a better advantage the associated foraminal stenosis, the deformity at the uncoversbral joint and the subchondral bone sclerosis.

at the C4 and C7 levels, the smallest AP diameter is usually at the C3 through C5 levels (62). It has been stated that all spinal stenosis that reduces the AP dimension to less than 10 mm could produce quadriplegia (64).

Although the uppermost cervical cord segments are nearly round, at most cervical levels the cord has an elliptical outline with its major axis transversely oriented. With encroachment of the cord by spinal stenosis, it is usually first flattened anteriorly by an encroaching osteophyte. With progression, the anterior median fissure becomes indented and widened until the cord assumes a kidney bean shape (Fig. 6-57) (48). The lateral funiculi may become tapered anterolaterally because of tension on the denticulate ligaments. The cord may become notched dorsally because of posterior white column atrophy. It has been estimated that a 30% reduction in cord cross-sectional area may be required to produce signs of ascending and descending tract degeneration (65).

### Thoracic Spine Abnormalities

Both thoracic disc herniation and thoracic spinal stenosis are rare compared with cervical and lumbar level disease. When thoracic

disc herniation does occur, it most frequently involves discs below T8 (66). The CT findings are similar to those of cervical levels, except that calcification of the disc protrusion is more common at thoracic levels. The causes as well as CT and MRI findings of thoracic spinal stenosis are similar to those at cervical levels.

### Lumbar Disc Herniation

The correlation of lumbar disc herniation with a patient's complaints of low back pain or sciatica is not always clearly established. It has been estimated that as many as 20% of patients with radiologic findings of disc herniation are asymptomatic (67). Furthermore, when disc herniation occurs in symptomatic patients, other findings are often present that also could explain the clinical findings.

Lumbar disc herniations occur most frequently posterolaterally because the annulus is thinnest in the posterior quadrants but reinforced in the midline by the posterior longitudinal ligament. Also, flexion is the most prevalent lumbar spine motion, which places greatest stress on the posterior part of the disc. When the disc herniates to the posterolateral direction, it frequently does not impinge on the spinal nerve roots emerging

**FIGURE 6-56.** Ossification of the posterior longitudinal ligament OPLL. **A:** Axial CT at the level of C3 demonstrates the calcification to the fibers of the posterior longitudinal ligament. There is narrowing to the central canal by the mass effect exerted by the enlarged calcified ligament. **B:** Sagittal multi-planar reformatted image. The *short arrows* at the flowing calcifications within the anterior longitudinal ligament. The calcification extends from C2 up to C7. The OPLL (*long arrow*) extends from C2 up to the proximal border of C5.

from the neural foramen to which the disc is related, because the nerve roots occupy the upper portion of the foramen, whereas the disc is situated in the anterior wall of the lower part of the foramen. Therefore, when the L5-S1 disc herniates posterolaterally, it frequently spares the L5 nerve roots, exiting through the upper portion of the L5-S1 neural foramen. Instead, it more commonly involves the S1 nerve roots that descend across the posterolateral aspect of the L5-S1 disc before their exit from the S1 sacral foramina. Less common lumbar disc herniations are placed centrally or far laterally. Central herniations can involve any or all of the rootlets of the cauda equina. The infrequent far

lateral herniations occur outside of the neural foramina. When present, they usually impinge on the ventral ramus that has just emerged from that foramen.

Noncontrast CT has been described as being accurate in diagnosing disc herniations. On CT examination, the herniated disc appears as a focal protrusion of the disc that displaces the epidural fat (Fig. 6-58). The herniated disc material is typically slightly hyperdense relative to the non-contrast-enhanced

**FIGURE 6-57.** Axial T2-weighted images in the same patient as in Figure 6-54. Note deformity to the cord that has assumed a bean shape in the transaxial plane. There is compression and increased signal intensity to the cord compatible with myelopathy (*arrow*).

**FIGURE 6-58.** Sagittal reconstructed image of a MDCT acquisition of the lumbar spine demonstrates a large disc protrusion.

**FIGURE 6-59.** **A:** Left parasagittal T2WI of the lumbar spine with an extruded disk at the L5-S1 segment. **B:** Axial T2WI demonstrates elevation of the thecal sac (TS) by the extrusion (E). There is mass effect and posterior displacement of the first sacral root (S1).

dural sac and its adjacent nerve roots. The dural sac or adjacent nerve roots may be seen to be indented, displaced, or compressed. In more lateral herniations, the soft-tissue material of the disc can encroach on the neural foramen or the extraforaminal soft tissues, where it also displaces fat, and here it may encroach on the dorsal root ganglion, spinal nerve, or its ventral ramus. Herniated lumbar discs may calcify or contain gas. Extruded disc fragments can become separated from the disc and are thus able to migrate superiorly, inferiorly, or laterally. A herniated disc should be distinguished from a bulging annulus. A bulging annulus is produced by dehydration and volume loss within the nucleus pulposus. In contrast to the focal protrusion of a herniated disc, the bulging annulus typically has a symmetrical smooth contour, bulging beyond all margins of the vertebral body.

On T1-weighted sagittal and axial MR images, the herniated lumbar disc appears as a moderate-signal-intensity intrusion into the high-signal-intensity epidural fat or on the moderate- to low-signal-intensity thecal sac or the lumbar nerve roots within their dural sleeves (Fig. 6-59A,B). Similarly, disc herniation into the neural foramen is visualized by a moderate-signal-intensity mass displacing the foraminal fat and encroaching on the dorsal root ganglion or nerve roots.

On T2-weighted sagittal MR images, the low signal intensity of a degenerated disc contrasts sharply with the high signal intensity of the nucleus pulposus of adjacent well-hydrated discs (Fig. 6-60). Any intrusion of the low-signal-intensity disc herniation on the thecal sac is well seen because of the high-signal-intensity myelographic effect of the CSF on T2-weighted images.

Discography remains a controversial diagnostic imaging modality. It appears that its major diagnostic value lies in the reproduction of the patient's specific pain on contrast injection of a given disc, with controls demonstrating that injection of

adjacent discs produces either no pain or foreign pain (68). Discography, especially when combined with CT, may provide information about degeneration and the extent of fissures and rupture.

### Lumbar Spinal Stenosis and Foraminal Stenosis

Like cervical stenosis, lumbar spinal stenosis is frequently precipitated by disc degeneration with subsequent marginal osteophytosis of the vertebral body ends, hypertrophic degeneration of the facet joints, and bulging of the ligamenta flava. Lumbar stenosis may be lateral, central, or combined. The lower lumbar vertebrae normally have shorter pedicles that cause the superior articular processes to intrude into the spinal canal

**FIGURE 6-60.** Small central extrusion (E) at the L5-S1 segment. Note decreased signal to the intervertebral disk when compared to the remaining intervertebral segments, a sign of degeneration.

**FIGURE 6-61.** MDCT of the lumbar spine in a patient with degenerative spondylosis and spinal canal stenosis. At the L4-5 level, there are hypertrophic degenerative changes of the facet joints and ligamentum flavum (*long white arrow*), which produce lateral stenosis, and hypertrophic changes of the articular process, which cause central stenosis (*short white arrow*). **A:** Bone windows. **B:** Soft-tissue windows that demonstrate to a better advantage the hypertrophied ligamentum flavum (*short arrow*). **C:** Soft-tissue windows and **D:** bone windows. There is congenital canal stenosis as well. Compression to the superior end plate of L1 is appreciated. **E:** Volume rendering reconstruction looking at the central canal demonstrates the significant narrowing to the central canal.

to cut off narrow lateral recesses (Fig. 6-61A–E). The lateral recesses are bordered by the pedicles laterally, the vertebral body anteriorly, and, most important, the superior articular processes posteriorly. The lateral recesses are occupied by the

nerve roots of the next spinal nerve to exit as they descend within their dural sleeve. Osteophytes that develop on the anteromedial margin of the superior articular processes of the next lower vertebra are most likely to encroach on the lateral

recess to produce lateral stenosis. Because the inferior articular processes of the next higher vertebra are situated posteromedial to the superior articular processes, osteophytes developing on their anterior margin are more likely to produce central stenosis. In central stenosis, any or all of the rootlets of the cauda equina can be encroached on. Vertebral body margin osteophytes and buckling of the ligamentum flavum can contribute to lumbar spinal stenosis.

Hypertrophic degenerative changes involving the facet joints can also encroach on the posterior aspect of the neural foramen and produce foraminal stenosis with compression of the nerve roots exiting that foramen. Therefore, hypertrophic degenerative changes involving a single superior articular process can involve the roots of two closely adjacent nerves, with the possibility of producing both foraminal and lateral spinal stenosis. With disc degeneration and loss of disc height, the neural foramen can be further compromised by the upward and forward displacement of the superior articular process into the upper part of the neural foramen, where the nerve roots are situated. In addition, because of the obliquity of the facet joint, the accompanying downward displacement of the inferior articular process of the next higher vertebra can produce retrolisthesis (i.e., backward displacement) of its vertebral body into the upper portion of the neural foramen.

By standard myelography, the protruding disc anteriorly and the bulging ligamenta flava posteriorly can produce an hourglass appearance of the thecal sac (Fig. 6-62). By CT, all osteophytes are clearly visualized, and measurements of the AP dimension of lateral recesses that are less than 3 mm are

**FIGURE 6-62.** Lumbar spinal stenosis caused by both protruding discs and bulging ligamentum flavum. Lateral myelogram showing the hourglass appearance of the thecal sac.

strongly suggestive of lateral stenosis (69). The hypertrophic changes producing central and foraminal stenosis are also well visualized. Sagittal reformations are especially helpful in evaluating foraminal stenosis.

Facet anatomy is well seen by MRI, with subchondral bone appearing as a signal void. On T1-weighted images, articular cartilage is visualized as a moderate-signal-intensity interval between the subchondral bone of the two articular processes. This becomes more signal intense on T2-weighted images. Facet joint degeneration appears as an irregularity or reduction in the thickness of the articular cartilage. Osteophytes are usually displayed as signal voids encroaching into the foramen, lateral recess, or spinal canal. Occasionally, osteophytes show high-signal-intensity interior, indicating the presence of marrow.

### Spondylolysis and Spondylolisthesis

Spondylolysis is a defect in the pars interarticularis, commonly involving the L5 and occasionally the L4 vertebrae. Most spondylolysis is thought to be produced by repetitive stress. The gravitational and muscular loads acting across the steep incline of the upper surface of the sacrum can be resolved into a shearing component, which tends to displace the L5 vertebral body forward on S1, and a compressive component at right angles to the superior surface of S1 (Fig. 6-63). In accordance with Newton's third law, S1 will exert an equal and opposite force against the inferior aspect of the L5 vertebral body. The tendency of L5 to be displaced forward on S1 is primarily resisted by the impaction of the inferior articular processes of L5 on the superior articular processes of S1. Again, Newton's third

**FIGURE 6-63.** The gravitational load (G) is applied across the lumbo-sacral junction. The equal and opposite forces acting on the inferior aspect of the L5 body and the anterior aspect of the inferior articular process of L5 cause shearing stresses to be concentrated on the pars interarticularis of L5 (curved arrows). This produces the stress fracture of spondylolysis.

**FIGURE 6-64.** Spondylolysis and spondylolisthesis. An oblique radiograph demonstrates a spondylolytic defect in the pars interarticularis of L4 (arrow). Note the intact neck in the “Scotty dog” outline in the L3 vertebra.

law dictates that there will be an equal and opposite force exerted against the inferior articular process of L5. The upward and forward force of the sacral body on the L5 body and the upward and backward force of the superior articular process of the sacrum on the inferior articular process of L5 cause shearing stresses to be concentrated on the pars interarticularis, and this can produce a stress fracture.

Spondylolisthesis is an anterior subluxation of one vertebral body on another. It can occur at any vertebral level, but the mechanics of the lumbosacral junction cause a higher incidence at this level. The most common cause at this level is spondylolysis, where the impaction of the inferior articular process of L5 or L4 will no longer be able to resist forward displacement of the vertebral body. Whether or not a spondylolisthesis follows a spondylolysis is largely determined by the resistance of the other supporting structures of the lumbosacral junction, which include the intervertebral disc, the anterior longitudinal ligament, and the iliolumbar ligaments. When they fail, the lysis becomes a listhesis.

Other causes of spondylolisthesis include degenerative changes in the facet joints and disc that produce joint instability, fractures, dysplasia of the upper sacrum or the neural arch of L5, generalized pathology such as Paget’s disease, or iatrogenically induced laminectomy or facetectomy (62).

On oblique plain films, spondylolysis is visualized as a break in the neck of the “Scotty-dog” outline, which is produced by the ipsilateral transverse process forming a nose; the ipsilateral pedicle, an eye; the pars interarticularis, a neck; the ipsilateral inferior articular process, a forelimb; the lamina, a

body; the contralateral inferior articular process, a hind limb; and the spinous process, a tail (Fig. 6-64). When spondylolysis is suspected clinically or on plain film studies, a volumetric CT with sagittal reconstruction, MR, or plain film examination with nuclear medicine scintigraphy can be useful for diagnosis (Fig. 6-65A,B) (70).

Spondylolisthesis is graded by the amount of subluxation, with grade I being a forward displacement of less than 25%; grade II, a forward displacement of 25% to 50%; grade III, a displacement of 50% to 75%; and grade IV, a displacement of greater than 75%. Grading the spondylolisthesis is usually accomplished by lateral plain films or sagittal reconstructed images in CT (Fig. 6-65C,D).

On CT, the defect of spondylolysis is differentiated from the facet joint interval by its location at the axial level of the pedicles rather than at the level of the neural foramen, as well as by the defect’s irregular margins and adjacent sclerosis. By MRI, the defect in the pars is visualized as a low-signal-intensity zone within the high-signal-intensity marrow of the pars.

## Spinal Trauma

Although much spinal trauma is well visualized on plain films, CT has a number of advantages over this modality. These include the demonstration of fractures not seen in plain films, an accurate determination of the amount of spinal canal encroachment by fracture fragments (Fig. 6-66A,B), the identification of neural foramen impingement by fractures involving its boundaries, and a more precise evaluation of facet disruption.

MR can display impingement on the dural sac or the spinal cord by bone fragments, as well as any resultant cord enlargement as a sign of cord edema or hemorrhage and cord atrophy. CT myelography can be used to diagnose post-traumatic cystic myelopathy because the cyst will take up the contrast and be displayed as a well-margined, homogeneous, high-density region within the cord. When MRI is not available or contraindicated, CT myelography can be used to assess the degree of spinal canal stenosis and cord compression.

CT also can augment the interpretation of the signs of vertebral instability seen on plain radiographs (Fig. 6-67A–C) (71). These signs include the following:

Vertebral displacements involving the whole vertebra or fracture fragments.

Widening of the interspinous interval, which implies injury to the posterior spinal ligaments secondary to hyperflexion injury.

Increased dimensions of the vertebral canal in the sagittal or coronal plane often evaluated by an increased interpedicle distance, which implies a complete disruption of the vertebral body in the sagittal plane.

Widening of the facet joint interval, which implies ligamentous disruption.

**FIGURE 6-65.** Spondylolysis and spondylolisthesis. **A:** Right parasagittal reconstruction of an MDCT demonstrates a spondylolytic defect in the pars interarticularis of L5 (PD arrow). **B:** Parasagittal reconstructed image from a volumetric CT demonstrating the pars defect in a patient with stage II spondylolisthesis (PD arrow). **C:** Midplane sagittal reconstruction demonstrates the grade II spondylolisthesis. **D:** Volume rendering, oblique posterior view demonstrating the pars defect (PD) and a normal pars (NP) above.

Disruption of the alignment of the posterior aspect of the vertebral bodies, such as occurs in burst fractures or lap-seatbelt fractures (Fig. 6-68).

T1-weighted sagittal and axial MR images provide the best evaluation of vertebral alignment and the bony and ligamentous boundaries of the spinal canal. They also allow the best delineation of the low signal intensity of a traumatic syringomyelia against the higher signal intensity of the surrounding spinal cord. T2-weighted sagittal MR images that produce a high-signal-intensity CSF provide the best estimate of the degree of encroachment of a bony fragment on the thecal sac or the spinal cord.

MRI has a number of advantages over other modalities for imaging spinal trauma. First, it permits evaluation of vertebral alignment at the cervicothoracic junction of the spine,

which is relatively inaccessible by other modalities. Second, it provides a means to evaluate adjacent soft-tissue damage. For example, hemorrhage in the prevertebral space that can occur with hyperextension injuries is identified on T2-weighted images as a high-signal-intensity area. MRI also identifies high-signal-intensity hemorrhage in the posterior paravertebral muscles that can occur secondary to hyperflexion injuries. In addition, MRI is the most sensitive modality for the assessment of ligamentous injuries as it detects edema within the supporting ligaments, a finding not assessed by any other imaging modality (Figs. 6-66 and 6-67C). Of importance is the fact that MRI provides a noninvasive means of evaluating the relationship of retropulsed vertebral body fragments or anteriorly displaced neural arch fragments to the spinal cord (Fig. 6-66C). In most centers, MRI has replaced myelography

**FIGURE 6-66.** MDCT visualization of spinal trauma. **A:** CT of a burst fracture of L1 shows displacement of a fracture fragment into the spinal canal (*arrow*). There is significant comminution to the superior articular surface of the vertebral body. **B:** Sagittal MPR reconstruction demonstrates the large fragment (*arrow*) extending into the spinal canal. There is mild compression of the superior end plate of L2. **C:** Sagittal T2-weighted MR image demonstrates increased signal intensity to the bone marrow of the L1 and L2 vertebral bodies due to the presence of edema and hemorrhage. There is posterior displacement of the conus and proximal cauda equina in the spinal canal. Increased signal to the conus (*arrow*) is compatible with a cord contusion.

as the procedure of choice for evaluating the effects of vertebral trauma on the spinal cord. Most important, MRI can evaluate the extent and type of spinal cord injury (71,72).

An acutely injured spinal cord tends to enlarge, thereby filling the spinal canal and displacing the epidural fat. This can be visualized by both CT and MRI. However, MRI provides the best means of evaluating the type of spinal cord trauma and its evolution. MRI is valuable in the early stages of spinal cord injury in determining the type of spinal cord injury and the prognosis for recovery. It can identify the level and completeness of cord transection by direct visualization of the

transection site. In the nontransected cord, it can discriminate cord hemorrhage from cord contusion with edema. Spinal cord contusion with edema causes high signal intensity on T2-weighted images within the first 24 hours of injury. Acute hemorrhage of less than 24 hours' duration appears as a low-signal-intensity area on T2-weighted images. Within a few days of the trauma, the subacute hemorrhage site becomes hyperintense on T2-weighted images as a result of the accumulation of paramagnetic methemoglobin (Fig. 6-69). Kulkarni et al. found that the type of injury visualized by MRI correlated with the patient's recovery of neurologic function (73). Those

**FIGURE 6-67.** **A:** Axial image at the C5 cervical segment. There is a burst comminuted fracture to the vertebral body. A fracture through the posterior arch is present as well. **B:** Sagittal MPR reconstruction demonstrates anterior collapse and posterior subluxation in relationship to the adjacent vertebral bodies. **C:** Sagittal T2-weighted MR shows increased signal to the vertebral body compatible with edema, prevertebral soft-tissue swelling (*arrow*) and edema (*arrow*) within the interspinous spaces as a secondary sign of ligamentous injury to the posterior supporting ligaments.

patients with cord contusion and edema exhibited significant functional recovery, whereas those with hemorrhage made little functional progress. Therefore, the MRI characteristics of the injury may provide the clinician with important prognostic data.

MRI is also invaluable for identifying late sequelae of spinal cord trauma, including myelomalacia and post-traumatic spinal cord cysts or syringomyelia. Myelomalacia is thought to develop within an injured segment of the spinal cord as a result of ischemia or the release of enzymes from damaged spinal cord tissues, or both (74). The myelomalacic area is made

up of the products of neuronal degeneration, scar tissue, and microcysts. It is thought that the myelomalacic areas become larger intramedullary cysts because the scar tissue about the injured cord tethers the cord to the dura so that the episodic changes in CSF pressure that occur during daily activities tend to be concentrated on the injured cord segment as stretching forces. It is hypothesized that these stresses cause coalescence of the myelomalacic microcysts into a progressively enlarging gross cyst. CSF is theorized to enter the cysts along enlarged perivascular Virchow-Robin spaces that connect the subarachnoid space to the cyst.

**FIGURE 6-68.** Sagittal T2-weighted image of the thoracic spine. There is a fracture dislocation (Chance fracture) at the C7-T1 interspace. There is bone marrow edema to the C7, T1, and T2 vertebral bodies and extensive prevertebral soft-tissue swelling. Edema is also appreciated within the posterior supporting structures. There is compression and edema (white arrow) to the cord extending from C6 up to the T2 segment.

On T1-weighted images, myelomalacia appears within the segment of the spinal cord near the area of injury as a region of lower signal intensity than the spinal cord but higher signal intensity than the CSF. It has indistinct margins with the surrounding spinal cord. In contrast, intramedullary cysts have signal intensity approximating that of CSF and sharply margined borders with the surrounding spinal cord or an adjacent area of myelomalacia. The development of an intramedullary cyst in a spinal cord patient whose clinical picture had previously

**FIGURE 6-69.** Sagittal T2-weighted image at the cervicothoracic junction in a patient with fracture dislocation at the C5-6 segment. There is compression and swelling to the cord. A focal area of decreased signal within the cord secondary to methemoglobin deposition associated to the acute bleed (arrow).

stabilized may cause the patient to develop progressive sensory and motor deficits. Although myelomalacia has no definitive treatment mode, a spinal cord cyst can be surgically decompressed with a shunt to achieve improvement or at least an arrest of the patient's neurologic deterioration. Therefore, the MRI distinction between cysts and myelomalacia is important. MRI can also be used in postoperative follow-up to ensure that the cyst has been fully decompressed and that the catheter is continuing to function to prevent reaccumulation of fluid within the cyst.

### Atlantoaxial Instability

Spine instability is the loss of the spine motion segment stiffness, where applied force produces greater displacement than normal, causing deformity and pain. Atlantoaxial instability can be produced by softening, laxity, or rupture of the transverse atlantal, alar, and apical ligaments of the dens (i.e., odontoid). These ligaments hold the odontoid in its proper position against the anterior arch of the atlas and below the level of the foramen magnum. Such ligamentous changes can be produced by rheumatoid arthritis, Down's syndrome, or traumatic rupture. Rheumatoid changes that destroy the articular cartilage and bone of the atlantoaxial joints can further increase the instability. Atlantoaxial instability also can be caused by odontoid abnormalities, such as an unfused apical portion of the odontoid (i.e., os odontoides), or by odontoid fractures. Normally, the cartilaginous radiolucent interval between the anterior arch of the atlas and the dens does not exceed 3 mm in the adult. With ligamentous abnormalities, lateral radiographs of the flexed cervical spine may show a posterior subluxation of the odontoid into the spinal canal that increases the atlas-dens interval to more than 3 mm. When posterior subluxation of the odontoid exceeds 9 mm, it is likely to compromise the spinal cord and produce neurologic abnormalities (75). There also can be a superior subluxation of the odontoid above the level of the foramen magnum that can cause death by impingement on the medulla or the vertebral arteries. These subluxations are well visualized by CT and MRI. MRI also can directly evaluate the ligaments. CT myelography and MR images in the axial or sagittal planes can assess the involvement of the spinal cord or medulla by the subluxation.

## BRAIN IMAGING

The following section will be dedicated to brain imaging relevant to rehabilitation. Emphasis is placed on the imaging of ischemic and hemorrhagic strokes, head trauma, and common degenerative diseases. The imaging of brain neoplasms and infections will not be covered in this section, as it is beyond the scope of this text.

### Stroke

The term *stroke* refers to both transient and permanent neurologic signs and symptoms of a nontraumatic vascular etiology. Imaging of acute stroke should help (a) exclude intracranial hemorrhage, (b) differentiate between irreversibly affected brain

tissue (“dead brain”) and reversibly impaired tissue (“tissue at risk”), which can benefit from early treatment, and (c) identify arterial stenosis or occlusion. Tissue at risk, or *penumbra*, refers to an area of reduced perfusion and loss of function, yet whose neurons are still viable. Therefore, once hemorrhage has been ruled out, timely reperfusion of this tissue with thrombolytics may prevent neuronal cell death and help re-establish normal function (76). CT continues to be the initial imaging modality for most acute stroke patients for three reasons. First, CT detects intracerebral hemorrhage with great specificity and sensitivity because freshly extravasated blood is more radiodense than either gray or white matter. Second, MRI is unable to detect the oxyhemoglobin that predominates in the hemorrhage in the early hours after a stroke because it is a nonparamagnetic substance. Third, the uncooperativeness of many acute stroke patients during the long MRI scan times and the incompatibility of critical monitoring equipment with strong magnetic fields often preclude early MRI examination. Current stroke diagnostic protocols follow a multimodal approach that can include non-contrast-enhanced CT, CT perfusion, CT angiography (CTA), conventional MRI, MR angiography (MRA), and diffusion- and perfusion-weighted MR imaging techniques, in order to establish early diagnosis and subsequently select appropriate therapy.

## ISCHEMIC STROKE

Cerebral ischemia can be produced by thrombosis of large extracranial or small intracerebral vessels, emboli originating from atherosclerotic plaques or thrombi within more proximal vessels or the heart. In addition, decreased perfusion of systemic origin, such as shock, decreased cardiac output, or respiratory failure can also cause cerebral ischemia with or without infarction.

Cerebral ischemia can be completely or partially reversible, or irreversible leading to neuronal cell death, commonly known as *infarction*. Once blood flow to the brain is decreased or interrupted for a sufficient period of time, usually in a well-defined vascular territory, the chemical pumps within the neuronal cell membranes cease to function adequately disturbing the normal electrolyte homeostasis. Extracellular water subsequently rushes into the affected neuronal cells. This cascade of events initially causes neurons to halt cellular function in an attempt to survive. This “stunned” cell population is potentially salvageable with prompt reperfusion. If adequate reperfusion does not occur in a timely fashion, irreversible neuronal cell deaths will occur. Edema related to infarction involves both gray and white matter and has certain CT and MRI findings.

Nonenhanced CT is the initial study of choice in patients with suspected stroke, as it is readily available, can be performed quickly, and is highly sensitive in the detection of cerebral hemorrhage. On nonenhanced CT, edema related to a cerebral infarction appears as a hypodense or low attenuation area, which means that it appears darker than expected. Early nonenhanced CT signs of ischemic cerebral infarction in the MCA territory are as follows: (1) Obscuration of the lentiform nucleus, some-

**FIGURE 6-70.** Obscuration of the lentiform nucleus. Nonenhanced CT shows effacement of the left lentiform nucleus (arrowhead). Compare with normal lentiform nucleus on the right (arrowhead).

times referred to as the *disappearing basal ganglia sign*, which can be seen as early as 2 hours after symptom onset (77) (Fig. 6-70). (2) Insular ribbon sign, which refers to hypoattenuation of the insular cortex (Fig. 6-71). (3) Hyperdense MCA sign, which refers to a fresh thrombus within the artery and can be seen as

**FIGURE 6-71.** Insular ribbon sign. CT changes of slight hypodensity, loss of normal gray-white matter differentiation, and effacement of overlying cortical sulci in the region of the right insula (arrow).

**FIGURE 6-72.** MCA hyperdense sign. Tubular hyperdensity at location of the left middle cerebral artery, compatible with intraluminal thrombus.

soon as 90 minutes after the event (Fig. 6-72). It is important to note that this sign implicates occlusion and not necessarily infarction. Nevertheless, nonenhanced CT is usually negative during the first few hours after an ischemic infarct, and it is only later that areas of hypoattenuation can be identified with associated effacement of the adjacent cortical sulci (Fig. 6-73).

**FIGURE 6-73.** Postinjury edema has peaked and the infarcted area is shown as a distinct hypodensity conforming to the territory of the right middle cerebral artery.

Edema reaches its peak at 3 to 5 days, and by this time non-contrast-enhanced CT typically demonstrates a well-defined hypodense area that usually corresponds to the vascular territory of one of the cerebral arteries or its branches. With large infarctions, brain swelling can eventually lead to brain herniation or obstructive hydrocephalus, which can be life threatening (Fig. 6-74A,B). With subsequent degeneration and phagocytosis of the infarcted brain tissue, there is volume loss that causes an increase in size of the overlying cortical sulci and underlying ventricles (78). When the infarction is caused by a systemically induced general reduction in brain perfusion, the infarcted areas correspond to the border zones between the territories of the major cerebral arteries because perfusion is most tenuous here (Fig. 6-75). Emboli can at times be directly visualized by noncontrast CT as hyperdensities within arteries. It is important to note that hemorrhage can not only occur *de novo* related to a hemorrhagic infarct, but that it can also occur within an ischemic infarct, as a consequence of reperfusion injury due to blood-brain barrier breakdown. When the latter occurs, it appears as a hyperdense mass within the hypodense edema of the infarct (Fig. 6-76).

Injection of intravenous (IV) contrast provides no brain enhancement in the first day or two after a stroke. Contrast enhancement must await sufficient damage to the blood-brain barrier. It reaches its peak at 1 to 2 weeks and usually ceases to occur after 2 or 3 months (79). The greatest vascular damage to intact vessels is at the periphery of the infarct. Therefore, contrast-enhanced CT frequently visualizes a contrast-enhanced ring about the infarcted area or in the immediately adjacent cortical gyri, a phenomenon known as *luxury perfusion* (Fig. 6-77A,B).

Conventional MRI is more sensitive and specific than CT for the detection of acute ischemic brain infarcts, within the first few hours after the onset of symptoms. On MRI, the edema of an early infarct is of low signal intensity on T1-weighted images with corresponding high signal intensity on FLAIR (fluid-attenuated inversion recovery) and T2-weighted images (Fig. 6-78A,B). In addition, there is loss of gray-white matter differentiation, sulcal effacement, and mass effect analogous to CT imaging findings. With the administration of IV gadolinium-diethylenetriamine pentaacetic acid (DTPA), a damaged blood-brain barrier can often be visualized as a hyperintense area on T1-weighted images. MRI is more sensitive than CT at detecting lacunar infarcts, which are small infarcts of less than 1.5 cm (78) typically located in the basal ganglia, periventricular areas, and at the brain stem (Fig. 6-79A,B). Lacunar infarcts are most commonly caused by hypertension or diabetes-induced arteriolar occlusive disease of the deeply penetrating arteries, such as the lenticulostriate branches of the middle cerebral arteries. MRI is also superior to CT in detecting ischemic infarcts of the posterior cranial fossa, because MR images are not degraded by osseous structures. Another powerful tool in the imaging stroke arsenal is diffusion-weighted MR imaging (DWI). The concept here is that water molecules normally move within tissues in a random fashion known as *Brownian*

**FIGURE 6-74.** **A:** Axial CT scan examination with large left subdural hematoma (*arrowheads*) and early subfalcine herniation (*long arrow*). **B:** Coronal multiplanar reformatted image (MPR) demonstrates to a better advantage the mass effect and the subfalcine herniation (*long arrow*). The subdural hematoma has a lentiform shape (*short arrow*).

*motion*. As was discussed earlier, acute stroke produces an electrolyte imbalance, which causes water molecules to rush into the intracellular compartment, where free random motion is no longer possible and therefore falling into a state

of restricted diffusion. DW images reflect restricted diffusion as a signal increase, which corresponds with a signal drop in its accompanying sequence, the apparent diffusion coefficient (ADC) map. The combination of increased signal

**FIGURE 6-75.** Axial diffusion weighted images (DWI) of an acute watershed infarct at the left superior frontal lobe. Increase signal intensity (*arrow*) represents restricted diffusion.

**FIGURE 6-76.** There is a hyperdense region at the left basal ganglia and thalamus surrounded by hypodense rim of edema, compatible with hemorrhagic transformation of an ischemic stroke. Patient had suffered an ischemic stroke 12 days earlier.

**FIGURE 6-77.** Axial CT images of the brain of patient with small focal areas of low attenuation representing lacunar infarcts within the right inferior basal ganglia (**A**) and within the caudate nucleus (**B**).

in the DW images and decreased signal in the ADC map is compatible with an infarct in the appropriate clinical setting, as other entities such as viscous abscesses and dense masses such as lymphomas can have a similar restricted diffusion pattern (Fig. 6-80A,B). One of the key features of DWI of acute cerebral ischemia is that it becomes positive as soon as

30 minutes after the insult and can remain positive for 5 days or more (80).

Nonenhanced CT is highly sensitive in detecting intracranial bleeds, which, in the setting of an ischemic stroke, represents hemorrhagic transformation. In MR imaging, T2\*-weighted gradient-echo sequences depict areas of hemorrhage as focal

**FIGURE 6-78.** Subacute ischemic infarct. **A:** Axial CT image demonstrates an area of decreased attenuation (*arrow*) within the head of the caudate nucleus. **B:** Axial proton density (PD) sequence. There is increased signal intensity (*arrow*) due to restricted diffusion characteristic of an infarct.

**FIGURE 6-79.** Lacunar infarcts. **A:** CT shows multiple bilateral lacunar infarcts as small hypodense areas (*arrows*). **B:** By MRI, these infarcts are shown as multiple hyperintense areas (*arrows*).

regions of low signal intensity, secondary to a phenomenon known as *blooming* (Fig. 6-81).

As was stated before, cerebral ischemia can be reversible. Tissue that is potentially salvageable with prompt recanalization is referred to as *penumbra*. The goal of modern stroke imaging is not merely to document an infarct and exclude hemorrhage, but rather to differentiate infarcted from salvageable tissue (penumbra) in an effort to guide thrombolytic therapy and save as much brain tissue as possible. CT and MR imaging techniques that are currently being used with this purpose in mind will be briefly discussed. CT perfusion is a technique in which a bolus of contrast is injected into the patient with simultaneous imaging of a slice of tissue, usually chosen at the level of the basal ganglia,

because it represents the three major vascular territories: Anterior, middle, and posterior cerebral arteries. The three main parameters obtained and compared throughout the slice are cerebral blood volume (CBV), cerebral blood flow (CBF), and mean transit time (MTT). In general terms, a mismatch between these parameters usually represents tissue suffering reversible ischemia or penumbra. MR perfusion is a contrast-dependent technique also utilized to determine the amount, if any, of salvageable brain tissue. In general terms, when a perfusion defect matches a diffusion defect, irreversible infarction has occurred. On the other hand, a perfusion-diffusion mismatch represents an area of reversible ischemia or penumbra, where infarction can possibly be avoided with timely thrombolytic treatment.

**FIGURE 6-80.** Ischemic infarct. Restricted diffusion is shown as increased signal intensity in the diffusion-weighted image (**A**) with corresponding signal drop in the ADC map (**B**) (*large arrows*).

**FIGURE 6-81.** Axial gradient echo T2\* image shows an irregular area of signal drop with surrounding high-signal-intensity edema at the left superior parietal lobe, compatible with a hemorrhagic stroke.

CTA is a technique that uses IV contrast to image extracranial and intracranial blood vessels. Different methods are utilized to reconstruct the arterial system, in an attempt to identify the cause of the patient's symptoms, usually an obstructing thrombus or embolus, which is seen as a cut-off in one or various vessels. CTA information is commonly used to guide intra-arterial or mechanical thrombolysis in stroke centers. Just as in CTA, MRA can also be performed following injection of IV contrast. Nevertheless, MRI has the added bonus of being able to perform angiograms without having to inject contrast material based on the MR properties of flowing blood; a useful proposition in patients with renal insufficiency. Contrast-enhanced MRA findings are analogous to CTA findings, nevertheless in non-contrast-enhanced (time-of-flight) MRAs, normal vessels are depicted as a flow void and intra-arterial thrombus is seen as an area of increased signal intensity (Fig. 6-82).

Cerebral venous thrombosis is caused by aseptic or septic etiologies, and can lead to infarction in a nonarterial distribution. This rare cause of infarction has characteristic imaging features. Whether the thrombosis involves a deep cerebral vein or a dural venous sinus, the thrombus can be detected on a noncontrast CT as a hyperdensity within the vein (81). The hyperdensity may have a hypodense center, implying a residual lumen. In a contrast-enhanced CT, a thrombus appears as a filling defect, with tortuous dilated collateral venous channels occasionally demonstrated around the thrombosed vein. By MRI, while the thrombus is still in the oxyhemoglobin stage, which is isodense to brain tissue, it can be suspected

**FIGURE 6-82.** Right middle cerebral artery thrombosis by MRA. Arrow points to vessel cut off.

by the absence of the normal flow void in that vessel. In the deoxyhemoglobin stage the thrombus is hypointense on T1, and in the later methemoglobin stage it becomes hyperintense on T1-weighted images. The venous thrombus typically does not proceed to the hemosiderin phase because it usually lyses spontaneously and flow is reestablished. Contrast and non-contrast-enhanced MR venography techniques can also be utilized to diagnose venous thrombosis (Fig. 6-83).

A stroke-like clinical presentation frequently encountered in the ER is a transient ischemic attack (TIA). A TIA is a functional neurologic disturbance usually lasting a few minutes, which clears completely within 24 hours. TIAs typically produce no CT or MRI findings, yet one third of these patients eventually will suffer a cerebral infarction, 20% of them within the first month after the episode. Some stroke centers perform an MRI to all patients who suffered a TIA, as occasionally acute infarcts are actually found.

## HEMORRHAGIC STROKE

A stroke is considered truly hemorrhagic if blood is found within the first 24 hours after initial symptoms. When blood is noted after this time, it is usually hemorrhagic transformation of an ischemic stroke, which is due to reperfusion injury.

Hypertension is the most common cause of intraparenchymal hemorrhage, which can also be caused by ruptured aneurysm, arteriovenous malformation, and more rarely, by infarction, neoplasms, blood coagulation defects, and cerebral

**FIGURE 6-83.** Deep venous thrombosis. Sagittal noncontrast T1-weighted image. Arrow points to a thrombus-filled hyperintense superior sagittal sinus. Arrowhead points to a thrombus filled hyperintense straight sinus.

arteritis (81). Common hemorrhage sites include the putamen and the thalamus, which receive their major blood supply from the lenticulostriate and the thalamogeniculate arteries, respectively.

Because freshly extravasated blood is more radiodense than gray or white matter, an acute hemorrhagic stroke is well visualized by CT as a hyperdense region usually conforming to an arterial distribution (Fig. 6-84A,B). The radiodensity of the blood clot increases over 3 days because of clot retraction, serum extrusion, and hemoglobin concentration. The extruded serum may form a hypodense rim around the hyperdense clot (Fig. 6-84C). As edema develops over 3 to 5 days, the hypodense rim may increase. Eventually, the hyperdensity of the clot gradually fades and usually disappears by 2 months, leaving only a narrow hypodense slit to mark the site where hemorrhage took place (Fig. 6-84D).

The appearance of hemorrhage by MRI depends on the state of the hemoglobin in the hemorrhage (81). The oxyhemoglobin present in a fresh hemorrhage is nonparamagnetic; therefore, very early hemorrhage is not detected by MRI. Within a few hours, the oxyhemoglobin will be converted to deoxyhemoglobin, which is a paramagnetic substance. Intracellular deoxyhemoglobin will cause acute hemorrhage to appear very hypointense on T2-weighted images and slightly hypointense or isointense on T1-weighted images (Fig. 6-85A). By 3 to 7 days, intracellular deoxyhemoglobin is oxidized to methemoglobin as the clot enters the subacute

phase. Although a subacute hemorrhage has several subphases in which the signal intensity of methemoglobin varies, in general methemoglobin appears hyperintense on both T1- and T2-weighted images (Fig. 6-85B). Because the conversion to methemoglobin begins at the periphery of the clot, early in the subacute phase a hemorrhage can have a hyperintense margin and a central hypointense region still containing deoxyhemoglobin. Eventually the entire region of subacute hemorrhage becomes hyperintense. Over several months, the methemoglobin is gradually resorbed and the clot develops a rim of hemosiderin-containing macrophages. Hemosiderin is hypointense on both T1- and T2-weighted images. Therefore, a chronic hemorrhage of several months duration often has a hyperintense methemoglobin center and a hypointense hemosiderin rim. Because the hemosiderin deposits remain indefinitely, an old hemorrhage of several years duration shows up as a totally hypointense area. Gradient-echo sequences have recently been added to many brain MRI protocols, as they are very sensitive in the detection of degrading blood products, which appear as areas of hypointensity. As can be seen, CT provides the very earliest information about cerebral hemorrhage, whereas MRI is the better technique for determining hemorrhage age.

## SUBARACHNOID AND INTRAVENTRICULAR HEMORRHAGE

Subarachnoid and intraventricular hemorrhage can be spontaneous, as in the case of a bleeding aneurysm or arteriovenous malformation, or secondary to trauma. CT is the imaging modality of choice for evaluating these types of hemorrhages because it detects the hemorrhage from its onset as a hyperdensity. However, subarachnoid hemorrhage is not as radiodense as epidural or subdural hemorrhage because the blood will be diluted by CSF. Unless blood replaces at least 70% of the CSF, the subarachnoid hemorrhage remains isodense to adjacent gray matter (82). When the volume of blood is sufficient to make the hemorrhage hyperdense, it accumulates in the extensions and expansions of the subarachnoid space. Subarachnoid hemorrhage appears as linear radiodensities within the sulci or fissures or as larger aggregations in the basal cisterns (Fig. 6-86). MRI will not visualize a very early hemorrhage when oxyhemoglobin, a nonparamagnetic substance, is the primary constituent, and thus CT is the study of choice in the very early stages. Subarachnoid and intraventricular hemorrhage can cause communicating hydrocephalus by virtue of red blood cells blocking the arachnoid granulations, the CSF resorption sites.

Aneurysms and arteriovenous malformations can be detected directly by contrast-enhanced CT and MRI, or by their flow void characteristics on non-contrast-enhanced MR images (Fig. 6-87A,B).

## Head Injuries

Head injury can be produced by direct contact or impact loading, where impacts either set a resting head in motion or stop a moving head, or can be produced by impulse or inertial loading,

**FIGURE 6-84.** CT evaluation of early and evolving hemorrhagic strokes. **A:** Recent hemorrhagic stroke has occurred in the distribution of the right posterior cerebral artery, which appears hyperdense (*arrows*). **B:** A massive hypertensive hemorrhage involving most of the interior of the left cerebral hemisphere with intraventricular hemorrhage, midline shift to the right, and herniation of the left hemisphere under the falx cerebri. **C:** A 5-day-old hemorrhagic stroke involving the lenticular nucleus shows a hyperdense hemorrhagic center (*arrow*) and a hypodense edematous rim (*arrowhead*). **D:** The same stroke patient displays replacement of the hyperdense hemorrhage with a narrow hypodense interval (*arrows*) several months later.

where the head is suddenly placed in motion or suddenly stopped without impact (83). Impulse or inertial loading is commonly referred to in the literature as *acceleration-deceleration mechanism*, which commonly produces shearing injuries. Fractures

and epidural hematomas are produced only by impact loading, but other types of head injury can be produced by either type of loading. Head injury is typically categorized as focal or diffuse. Focal injuries include extracerebral hemorrhages such as

**FIGURE 6-85.** MRI evaluation of hemorrhagic stroke. **A:** An acute hemorrhagic stroke involving the occipital lobe appears hypointense (*arrow*). **B:** In the subacute phase, the same area appears hyperintense (*arrow*).

epidural or subdural hematomas, intraparenchymal hematomas, cerebral contusion or laceration, and fractures. Diffuse brain injuries include diffuse axonal injury, diffuse cerebral swelling, and edema. Furthermore, traumatic head injuries can be classified as primary or secondary, where primary injuries are a direct result of trauma such as contusions and diffuse axonal injury, and secondary injuries are an indirect sequela of trauma such as edema, infarctions, or herniations.

**FIGURE 6-86.** Subarachnoid hemorrhage secondary to a right middle cerebral artery aneurysm. CT shows this condition as hemorrhagic radiodensities within sulci and cisterns (*arrow*).

CT is typically the imaging modality of choice for patients suffering head trauma, because it is very accurate at detecting the depressed fractures and acute hematomas that require emergency surgery. Its other advantages include rapid scanning with continuation of close monitoring of critically injured patients. MRI has the disadvantages of longer scans, high susceptibility to motion artifacts by uncooperative patients, inability to detect very recent hemorrhage, and difficulty evaluating fractures because of the signal void characteristics of cortical bone.

## EPIDURAL HEMATOMA

Epidural hematoma is caused by tears of the middle meningeal artery or vein, or of a dural venous sinus. The blood accumulates in the interval between the inner table of the calvarium and the dura by gradually stripping the dura from its bony attachment. CT visualizes the epidural hematoma as a well-localized biconvex radiodense mass (83) (Fig. 6-88). It is commonly, though not invariably, associated with a skull fracture. It causes mass effect upon the adjacent brain parenchyma with effacement of the underlying sulci, compression of the brain and ventricles, and possible contralateral midline shift. It is important to note that midline shift is a secondary injury caused by subfalcine herniation, which is herniation of the cingulate gyrus under the falx cerebri, and can eventually lead to ipsilateral anterior cerebral artery infarction. When there is a question about whether the mass might be intraparenchymal,

**FIGURE 6-87.** **A:** CT of an anterior cerebral artery aneurysm (*arrow*) that produced a subarachnoid hemorrhage with secondary hydrocephalus. **B:** Axial collapse image of a time of flight (TOF) MR angiogram in a different patient. The *arrow* points to a large aneurysm arising from the left anterior communicating artery.

contrast injection enhances the dura, establishing the epidural position of the clot. As the clot lyses over the next few weeks, it shrinks and changes to isodense and then hypodense relative

to the brain. The inner aspect of the clot vascularizes, and this may produce a thicker rim of enhancement on late contrast studies. The overlying dura may calcify. Epidural hematoma may be associated with subdural, subarachnoid, or intraparenchymal hemorrhages.

**FIGURE 6-88.** Epidural hematoma. Nonenhanced CT scan of the head shows a left parietal biconvex extra-axial hyperdensity (*arrow*).

## SUBDURAL HEMATOMA

Subdural hematoma is most commonly caused by acceleration-deceleration shearing stresses that rupture the bridging veins that extend from the movable brain to the fixed dural venous sinuses. The blood accumulates in a pre-existing but essentially volumeless subdural space. Normally, the pressure of the CSF holds the arachnoid in contact with the dura, thereby creating a real interval that is without significant volume. Because the subdural space is a real space surrounding all external surfaces of the brain, subdural hemorrhage tends to spread extensively over many aspects of the brain surface.

On CT examination, the typical acute subdural hematoma appears as a diffuse crescent-shaped radiodensity that may extend onto many surfaces of the brain, including the cerebral convexity, skull base, interhemispheric fissure, upper or lower surface of the tentorium, and area around the brain stem (Fig. 6-89). One way to differentiate subdural from epidural hematomas is that subdural hematomas cross sutures lines yet do not cross midline, whereas epidural hematomas do not cross suture lines yet can cross midline. There are two ways of classifying subdural hematomas based on their changing

**FIGURE 6-89.** Bilateral panhemispheric chronic subdural hematomas with superimposed acute bleed and hematocrit levels (arrows).

radiographic appearance over time (83). One scheme divides them into acute (i.e., more radiodense than adjacent gray matter), subacute (i.e., isodense to gray matter), and chronic (i.e., hypodense to gray matter). Another scheme simply lumps the subacute and chronic into the chronic category. The subdural hematoma typically effaces the adjacent gyri, produces inward displacement of the gray-white matter junction, and may compress the ventricle or cause brain herniation under the falx or through the tentorium.

As the subdural hematoma ages, the hemoglobin protein producing its radiodensity is broken down and removed, and a vascular granulation tissue develops along its inner surface. Over a few weeks, the subdural hematoma usually becomes isodense or hypodense to gray matter (84). Because of volume loss, the chronic subdural hematoma may lose its concave inner border and become more focal, even occasionally assuming a biconvex outline. Isodense subdural hematomas are more difficult to discriminate. Their presence can be implied indirectly by their mass effects on the underlying brain. An injection of contrast material will enhance both the vascular membrane and the displaced cortical vessels, allowing discrimination of the hematoma from the adjacent cortex.

Patients who present first with a chronic subdural hematoma may have no recollection of any antecedent trauma because the traumatic episode may have been so slight that it was forgotten. Chronic hematomas commonly involve the elderly, where loss of cerebral volume puts the bridging veins under increased stress and makes them more susceptible to rupture by minor trauma.

MRI has valuable unique imaging properties that make it very sensitive to the detection of some extracerebral hemorrhages. First, the high signal intensity that subacute hematomas display on T1- and T2-weighted images makes MRI more sensitive than CT for detecting hematomas that are isodense by CT (73). Even chronic subdural hematomas remain hyperintense to CSF and gray matter for several months, which is long after they have become isodense or hypodense on CT. Also, the ability of MRI to discern the displaced signal voids of cortical or dural vessels facilitates the identification of small extracerebral hemorrhages. In addition, when the hematoma collects around the obliquely placed tentorium, axial CT images may average it into adjacent tissues. In these cases, the multiplanar imaging properties of MRI can be very valuable. Also, small hematomas next to the calvarium can be better seen by MRI because they are contrasted against the osseous signal void.

## CONTUSIONS AND INTRAPARENCHYMAL HEMORRHAGE

Focal parenchymal injuries such as contusions and intraparenchymal hemorrhage usually develop as a result of contact of the brain with the osseous walls of the cranial cavity. The coup-type injuries occur at the point of contact, and the contrecoup injuries occur on the opposite side of the brain. Contusions often occur in areas where the walls of the cranial cavity are irregular, such as the anterior and middle cranial fossae. Therefore, frontal and temporal lobe contusions are common as the brain glides along these irregular surfaces (85) (Fig. 6-90A,B).

Cerebral contusions are heterogeneous lesions containing edema, hemorrhage, and necrosis, with any element predominating. When blood makes a major contribution, the contusion appears on CT as a poorly delimited irregular area of hyperdensity. A contusion with mostly edema or necrosis may not be detectable immediately, but after a few days it appears as a hypodense region. Where there is a general admixture of elements, contusions may have a heterogeneous density. Old contusions appear as hypodense areas. By MRI, the edematous and necrotic areas have low signal intensity on T1-weighted images and high signal intensity on T2-weighted images, and thus MRI is more sensitive than CT in identifying these non-hemorrhagic contusions. The areas of hemorrhage in a contusion older than a few days will be hyperintense on both T1- and T2-weighted images.

Intraparenchymal hemorrhage differs from contusions by having better demarcated areas of more homogeneous hemorrhage. The CT and MRI characteristics of acute and evolving intraparenchymal hemorrhage are the same as for hemorrhagic stroke.

## DIFFUSE BRAIN INJURIES

Diffuse brain injuries include diffuse axonal injury, diffuse cerebral swelling, and edema. Diffuse axonal injury is produced by high shearing stresses that occur at different parts of the brain,

**FIGURE 6-90.** **A:** Nonenhanced CT scan shows a small left frontal hyperdense hemorrhagic foci (*arrow*). Acute extra-axial bleed is also noted (*arrowhead*). **B:** Left temporal post-traumatic hemorrhagic contusions (*arrow*). Overlying acute extra-axial bleed is noted (*arrowhead*).

including at the gray matter-white matter interface. These shearing stresses cause axonal stretching commonly involving the corpus callosum, anterior commissure, and upper brain stem. Blood vessels may or may not be disrupted. When vessels are uninterrupted, the scattered small areas of edema are best demonstrated by T1-weighted MR images as slightly hypointense or isointense regions that become hyperintense on T2-weighted images. When vessel disruption produces hemorrhages, they appear early on CT as multiple sites of hyperdensity (Fig. 6-91).

Diffuse cerebral swelling occurs with many types of head injury. It is thought to be produced by a rapidly increased volume of circulating blood. By MRI and CT, the general brain enlargement is visualized by an obliteration or encroachment of the normal CSF spaces: the cortical sulci, the perimesencephalic and basal cisterns, and the ventricles (85). By CT, the enlarged brain may show slightly increased density.

In generalized cerebral edema, the enlarged brain also encroaches on the CSF spaces, but by CT the edema produces a generalized hypodensity that usually takes longer to develop than diffuse cerebral swelling (Fig. 6-92). The edema may obscure gray matter-white matter boundaries.

Both diffuse brain swelling and generalized cerebral edema are emergencies, because if not treated promptly they may lead to brain herniation sometimes with fatal outcomes.

**FIGURE 6-91.** Diffuse axonal injury. Nonenhanced CT scan shows hemorrhagic foci at the genu of the corpus callosum (*arrows*).

**FIGURE 6-92.** Diffuse brain edema. Nonenhanced CT scan shows diffuse hypodensity with sulci effacement and loss of gray/white matter differentiation. Mass effect is causing almost complete obliteration of the ventricular system. Compare low parenchymal attenuation with normal cerebellar density.

## PENETRATING TRAUMA

Bullets and other types of penetrating objects will cause brain laceration by both the penetrating objects and the fragments of subcutaneous tissues, bone, and dura driven into the brain. The imbedded fragments of the foreign object and bone are well visualized by CT, as are the accompanying cerebral edema and various types of intracerebral or extracerebral hemorrhage.

## COMPLICATIONS OF BRAIN INJURY

Brain injuries may be accompanied by a number of late or long-term complications. These secondary brain injuries include cerebral herniations, which may occur under the falx cerebri or through the tentorium. Herniations can cause compression of adjacent brain substance or vessels, with the production of secondary signs and symptoms (Fig. 6-93). Penetrating injuries or fractures can injure nearby large or small vessels, producing thrombosis, embolism, traumatic aneurysm formation, or internal carotid–cavernous sinus fistula. Basal skull fractures involving the dura and arachnoid can

**FIGURE 6-93.** Nonenhanced CT scan shows a left MCA infarct with mass effect causing contralateral midline shift (*arrow*) corresponding to subfalcine herniation.

cause CSF leaks that show up as CSF rhinorrhea or otorrhea. Local or diffuse brain swelling can compress the cerebral aqueduct or fourth ventricle, producing obstructive hydrocephalus. Subarachnoid hemorrhage may obstruct CSF resorption and cause a late-developing communicating hydrocephalus. Focal cerebral atrophy can occur at sites of infarction, hemorrhage, or trauma. Generalized atrophy can follow diffuse injuries and can be demonstrated by an increased size of sulci, fissures, cisterns, and ventricles.

## Degenerative Diseases of the CNS

Degenerative diseases of the CNS include the wide spectrum of gray and white matter diseases, general degenerative changes of aging, and the dementias.

## WHITE MATTER DISEASES

White matter diseases can be divided into demyelinating diseases, in which the white matter is normally formed and then pathologically destroyed, and dysmyelinating diseases, in which there is usually a genetically determined enzymatic disorder that interferes with the normal production or maintenance of myelin (86). The enzymatic disturbances are relatively rare; therefore, their imaging characteristics will not be described.

**FIGURE 6-94.** T2-weighted (**A**) and FLAIR (**B**) MRI demonstrates the periventricular demyelinating plaques of MS as hyperintense areas (*arrows*) adjacent to the anterior horns and atria of the lateral ventricles.

The most common of the demyelinating disorders is multiple sclerosis (MS). The demyelinating plaques of MS are better visualized by MRI than by CT. In fact, MRI has become the primary complementary test to confirm a clinical diagnosis of MS. It also provides a quantitative means of evaluating the present state of a patient's disease and a mode of following its progress (87). Although the T1-weighted MR images are usually normal, the FLAIR and T2-weighted images demonstrate MS plaques as high-signal-intensity areas. These are most frequently seen in the periventricular white matter, especially around the atrium and the tips of the anterior and posterior horns of the lateral ventricles (Fig. 6-94A,B). The high-signal-intensity plaques also can be seen in other white matter areas of the cerebral hemispheres, the brain stem, and even the upper spinal cord. When these lesions are seen in patients younger than 40 years of age, they tend to be relatively specific for MS (86). In patients more than 50 years of age, the MRI findings of MS are similar to findings in some aging brains, and correlation with the clinical findings helps establish the diagnosis. Recent MS plaques that involve damage to the blood-brain barrier frequently enhance with the use of IV gadolinium-DTPA (Fig. 6-95).

CT demonstrates MS plaques with less reliability than does MRI. On CT, these plaques appear as areas of hypodensity. Recent plaques in the acute phase of an exacerbation of the disease will have damage to the blood-brain barrier, and IV contrast will then enhance the periphery of the lesion. In the chronic plaque, no contrast enhancement occurs on CT or MRI. Other demyelinating diseases, although numerous, are of relatively low incidence and therefore are not described.

**FIGURE 6-95.** Active MS. T1 gadolinium enhanced MR image shows periventricular enhancing MS plaques (*arrows*).

## GRAY MATTER DISEASES

At present, MRI is being used clinically to discriminate a number of movement disorders that are characterized by changes in the size or iron content of a number of deep gray matter nuclei (88). Normal nuclei that contain high iron levels, such as the globus pallidus, reticular part of the substantia nigra, red nucleus, and dentate nucleus of the cerebellum, appear hypointense on T2-weighted images. In Parkinson's disease, T2-weighted MRI shows a hypointensity in the putamen that may exceed the normal hypointensity of the globus pallidus. In Huntington's chorea, MRI consistently shows atrophy of the head of the caudate with associated dilation of the adjacent frontal horn of the lateral ventricle. Some patients with Huntington's chorea also show a hypointensity of the caudate or putamen on T2-weighted images and atrophy predominating in the frontal lobe. Some forms of secondary dystonia show increased signal intensity of the putamen and caudate in T2-weighted images.

### Age-Related Changes and Dementing Disorders

The aging brain is characterized on CT or MRI as demonstrating volume increases in both cortical sulci and ventricles (Fig. 6-96). T2-weighted MR images also frequently display small areas of hyperintense signal along the anterolateral margins

**FIGURE 6-96.** A case of cortical atrophy of aging as seen by CT. Enlargement of cortical sulci and sylvian fissures (arrows) with ex vacuo ventricular dilatation (arrowheads).

of the anterior horns of the lateral ventricles. These changes may or may not be associated with neurologic findings.

Patients with Alzheimer's disease (AD) and other dementing disorders consistently show these age changes, but because many normal elderly do also, these changes cannot be used to diagnose AD. However, the absence of these findings typically excludes AD. Findings more specifically related to AD are those involving the temporal lobe. The earliest findings in AD involve atrophy of the temporal lobe with dilation of the temporal horn of the lateral ventricle, as well as dilation of the choroidal and hippocampal fissures caused by atrophy of the hippocampus, subiculum, and parahippocampal gyrus (89).

## EMERGING IMAGING TECHNOLOGIES OF INTEREST TO THE PHYSIATRIST

### Advanced MR Imaging Techniques

Since the advent of medical imaging using nuclear magnetic resonance (NMR), there has been a continuous advance in this technology with improvements in spatial resolution, as well as the introduction of new methods that allow for the rapid acquisition of images and the ability to image different aspects of dynamic function within the imaged tissues. Most of the initially introduced techniques involved the imaging of static structural characteristics at different points in parenchymal tissue. Proton density imaging basically reflects the concentration of water and the electrochemical environment of the water-based protons in the tissues. When water-based protons are actively in motion during the standard MRI imaging sequence, a "flow artifact" is created. However, if one is actually interested in the imaging of proton movement, then the flow artifact becomes a flow signal to be recorded. This is the basis for both magnetic resonance angiography (MRA), which is actually the imaging of proton flow within the vascular spaces, and for diffusion-weighted imaging (DWI) and diffusion-tensor MR imaging (DTI), which is the imaging of the molecular diffusion of water molecules through tissue. When techniques are employed to image the diffusion of specific molecular species related to tissue metabolism, one can develop MR-based imaging techniques that allow one to image the active perfusion of tissues as well as their metabolic activity. This is the basis for perfusion-weighted and functional MRI (fMRI). Functional changes in the brain occur at relatively rapid rates during performance, and in order to image these changes, images must be acquired at a very rapid rate. Echo planar imaging (EPI) is a method for MR image acquisition that optimizes the image acquisition algorithm so that an entire image is acquired within a single TR period. EPI permits the acquisition of tomographic images at "video" rates of 15 to 30 images a second or down to as low as 20 ms per image, depending on the pulse sequence employed. EPI has been particularly important for the advancement of fMRI of the brain but is also used in DWI to reduce motion artifact.

## MAGNETIC RESONANCE ANGIOGRAPHY

Conventional angiography uses x-ray methods that involve introduction of an iodine-based radio-opaque dye into the vascular space through an intravascular catheter, followed by imaging of the distribution of the dye within different vascular compartments. This technique involves the invasive introduction of the dye via intra-arterial catheterization and potential problems resulting from the physical introduction and threading of the catheter, as well as allergic reactions to the dye. The technique can be used to produce a structural image of a vascular tree but does not provide direct information regarding the relative flow of the blood within the tree. MRA, on the other hand, involves no introduction of dye, except in the contrast-enhanced technique described later, and no need for invasive catheter introduction. The technique takes advantage of the principle of signal intensity attenuation from a region in which the imaged protons are actively in motion, producing a dark-signal “flow void” that marks a vascular structure containing moving blood seen on a standard T1-weighted image. MRA produces images of dynamically flowing blood, with the intensity of the image signal being proportional to the actual blood flow velocity. MRA, therefore, provides a dynamic image of circulatory flow rather than a static image of a vascular structure as is obtained with conventional x-ray angiography. Generally, there are three different methods used to produce MRA

images: time-of-flight, phase contrast angiography, and contrast-enhanced angiography.

As was described above, time-of-flight imaging involves utilizing the normal loss of signal produced by moving intravascular protons, seen as a signal drop or “void,” to create images of the vascular tree.

Phase-contrast angiography involves the application of a bipolar magnetic field gradient pulse. Two imaging sequences are performed in which the first has a positive bipolar gradient pulse and the second has a negative bipolar gradient pulse and the raw data from the two images are then subtracted. The signals emitted by stationary spin sources cancel out, whereas the signals emitted from flowing sources will add up. The net effect is to produce an image of proton spins that are flowing.

In contrast-enhanced MRA, the imaging of the vessels relies on the difference between the T1 relaxation time of the blood and that of the surrounding tissues after a paramagnetic contrast agent has been injected into the blood. The agent reduces the T1 relaxation time in the blood relative to the surrounding tissues. This technique generally provides a higher quality imaging of structural vascular anomalies comparable to that obtained with x-ray angiography. In addition, MRA techniques are normally obtained in conjunction with conventional MRI sequences, and therefore information regarding surrounding brain parenchyma also becomes available. An example of a normal contrast enhanced MRA is shown in (Fig. 6-97A,B).

**FIGURE 6-97.** (A and B) Normal magnetic resonance angiography (MRA).

**FIGURE 6-98.** Magnetic resonance angiogram (MRA). The left internal carotid artery is occluded (*arrow*). The right internal carotid artery is normal.

The disadvantages of MRA over conventional x-ray angiography are that the images are not quite as clear using MRA, the time for acquisition of the study is significantly longer with MRA, and the study involves an extended period of time in the scanning tube, which may not be tolerated by claustrophobic patients.

An example of an MRA study of the head demonstrating occlusion of the left internal carotid artery is shown in Figure 6-98.

## FLUID-ATTENUATED INVERSION RECOVERY IMAGING

Another MR imaging pulse sequence that has been usefully applied is the so-called fluid-attenuated inversion recovery (FLAIR) imaging method. In this imaging technique, T2 is heavily weighted with a short TE (e.g., 160 ms) and a very long TR (e.g., 10,000 ms) with the selection of an inversion interval, TI, so as to null out any mass fluid-containing spaces such as the cerebral ventricles or the subarachnoid space overlying the cortical surface. This creates a significant contrast between CSF and parenchymal brain tissue that enhances the identification of edema, periventricular white matter lesions, as well as cortical and gray-white matter junction lesions. It has been shown to be useful in conditions involving the subcortical white matter such as MS (90). Studies using FLAIR MR sequences to

**FIGURE 6-99.** MR FLAIR image of an acute left middle cerebral artery stroke.

evaluate white matter lesions in severe traumatic brain injury (TBI) suggest that the white matter lesion “load” associated with diffuse axonal injury, as detected by this sequence, correlates with the severity of the clinical presentation and the eventual clinical outcome (91–93). FLAIR images are generally more sensitive in the identification of white matter lesions than conventional T2-weighted images or T2-fast spin echo techniques. However, the technique is also subject to CSF pulsation artifact and to vascular flow artifact, which can limit its utility in certain situations. A FLAIR image of a left middle cerebral artery territory stroke is shown in Figure 6-99 compared to a corresponding T2-weighted image (Fig. 6-100).

## DIFFUSION-WEIGHTED IMAGING

Diffusion is a physical property of molecules whereby they move randomly via Brownian motion and spread out through a medium in accordance with their thermal energy. The rate of diffusion for a particular molecule in a particular environment is measured by the diffusion coefficient. Molecular diffusion is influenced by concentration (i.e., chemical) gradients, as well as by mechanical tissue structure that can confer a directional (“anisotropic”) component. For example, in muscle or in cerebral white matter, anisotropic tissue structure creates a preferred pathway for water diffusion parallel to muscle or nerve fibers and the direction of diffusion is largely uniform across each imaged voxel. Diffusion of polarized molecules may also be influenced by an electrical potential gradient. Diffusion imaging is performed in the same general manner as phase-contrast angiography, described earlier, except that the amplitudes of

**FIGURE 6-100.** MR T2-weighted image of an acute left middle cerebral artery stroke. Note increased signal to the subcortical white matter of the left temporal lobe and frontal lobe operculum and decreased gray white matter differentiation due to parenchymal swelling and edema (arrow).

the bipolar magnetic field gradients are increased greatly so as to be able to image the relatively small distances and slower velocities associated with molecular diffusion as opposed to blood flow. Rapid image-acquisition techniques such as echoplanar imaging are used to limit the influence of motion artifact. The direct MR signal cannot differentiate between diffusion-related motion in extracellular fluid, blood flow, perfusion, and tissue-pulsation-related motion. Thus, what is being imaged is not actually a true tissue diffusion coefficient, but rather an ADC. Since diffusion-weighted images are strongly T2-weighted because of the long probe times of the magnetic field gradients, a calculation can be performed to separate T2 relaxation effects from diffusion-related changes in the signal and derive the ADC. A map of ADCs can then be calculated for specific regions of interest from the diffusion-weighted image.

DWI is most usefully applied to the problem of early detection of brain infarction. The diffusion coefficient of ischemic brain tissue rapidly *decreases* within minutes of onset of tissue ischemia (94). While a standard T2-weighted MRI examination can detect brain ischemia/infarction as early as 3 hours after onset (Fig. 6-100), DWI can detect ischemia within minutes (Fig. 6-101). One possible explanation for this rapid change is that cytotoxic ischemia causes a movement of water from extracellular to intracellular spaces as the cells rapidly swell due to a failure of the sodium ATP-dependent

pump. This membrane-based pump, which appears exquisitely sensitive to ATP availability, normally maintains water equilibrium across cell membranes and thereby regulates cell volume by controlling intracellular and extracellular cation concentrations. The resulting decrease in average diffusion of water-dependent protons in the ischemic region is detected as an area of increased signal intensity on the diffusion-weighted MR image. Signal intensity rapidly rises with tissue ischemia with the diffusion coefficient for water reduced by as much as 50% within minutes after onset of ischemia. With the emergence of new early interventions for acute cerebrovascular thrombosis, improved patient selection and triage at a very early point in the evolution of cerebral ischemia could be achieved with DWI. Furthermore, the changes noted during acute ischemia on DWI, particularly when compared with MR perfusion images described earlier, may indicate reversible tissue dysfunction and may be very helpful in selecting patients for early thrombolytic intervention for acute cerebrovascular thrombosis (95,96).

Additional applications of DWI involve the assessment of *restricted* diffusion due to the anisotropic structure of surrounding tissue such as the myelinated fiber tracts in cerebral white matter and in the spinal cord. The assessment of restricted diffusion involves computing an ADC for each of six different directions for each voxel in the image and using this to derive a diffusion *tensor*. This technique has been called *diffusion tensor imaging* (DTI). Using geometric methods to determine the degree of loss of anisotropic diffusion in subcortical white matter, it is possible to document white matter disruption such as focal dislocation, tearing, swelling, and infiltration. It is also possible to map out the structure and direction of major subcortical white matter tracts using a technique called *diffusion tensor tractography* (97). DWI and fMRI have been used together to map out altered white matter anatomy and to identify eloquent cortical regions for movement and language generation in process of planning brain tumor excisions. Imaging information can be used so that displaced but intact fiber tracts can be preserved and critical cortical regions can be left unharmed. There is now also ongoing active research to evaluate the application of DWI to the assessment and recovery from diffuse axonal injury due to TBI (98,99). Recent studies with limited numbers of patients suggest that DWI may be a helpful technique for detecting the presence and localizing the zones of damage in TBI due to diffuse axonal injury when standard imaging methods show no abnormality (100–102). This is clearly an evolving area with some currently used imaging applications and important future research.

## IN VIVO MAGNETIC RESONANCE SPECTROSCOPY IMAGING

Although most of the MR signal that is typically examined in clinical imaging comes from water-based protons, it is possible to study specific resonances from other sources in

order to image other metabolically important molecules in the tissue. Although it is relatively easy to obtain a detailed NMR spectrum from a bulk sample as is typically done in NMR-based analytical chemistry, it is much more difficult to obtain the full spectrum from a spatially restricted volume of tissue. A number of different approaches have been taken to develop spectroscopic imaging techniques that would permit the recording of the NMR spectrum for each voxel in an image. However, because the concentration of most metabolic molecular species of interest (e.g., lactic acid) is typically several orders of magnitude less than that of water or fat in different tissues, the proton-NMR signals from water and fat must be suppressed when performing proton spectroscopy of metabolites, and large magnetic fields are also required to permit improved signal-to-noise ratio so that these much smaller spectral peaks can be registered clearly. At present, *in vivo* MR spectroscopy imaging is being used in a wide range of clinical as well as research applications.

## PERFUSION-WEIGHTED IMAGING AND FMRI

PWI of the brain is obtained by rapidly injecting a paramagnetic dye (e.g., gadolinium) intravenously and imaging the appearance of the dye in perfused brain tissue. Its utility in stroke imaging, particularly when used in conjunction with DWI, was discussed earlier in the section on ischemic stroke. Functional MRI depends on the coupling of neuronal firing to local changes in metabolic rate that are, in turn, linked to changes in local perfusion of normal brain tissue. In a locally active region of brain tissue, there is an increase in oxygen extraction to support the increased metabolic rate of the tissue. However, there is also an increase in local CBF to support the active region, which increases oxygen delivery to the area to the point where it exceeds that which is actually required. There is therefore a relative *decrease* in the local concentration of deoxyhemoglobin at the postcapillary level in activated tissue. Deoxyhemoglobin contains iron and is paramagnetic, thus diminishing signal intensity on a T2-weighted image. Since deoxyhemoglobin is decreased in activated tissue, there is a net increase in signal intensity in this region on the T2-weighted image. This is a small signal but can be recovered from the background by averaging together several images obtained by rapid-acquisition EPI methods. The images are obtained while the subject is engaged in performing a specific continuous activating task such as repetitively moving the fingers of one hand or performing an extended cognitive task. This fMRI technique is referred to as *blood-oxygen-level-dependent imaging*, or BOLD. A number of other techniques have also been developed for use in fMRI applications (103).

Table 6-1 provides a brief description of the various MR-imaging techniques that have been touched on in this chapter and provides a synopsis of their different applications and limitations.

## Susceptibility-Weighted Imaging

Susceptibility-weighted imaging (SWI) is a 3D gradient-echo sequence, which provides high-resolution images based on local tissue magnetic susceptibility and on BOLD effects (104–105). Magnetic susceptibility is related to loss of signal in voxels with magnetic field nonuniformities, due to greater T2\* decay. SWI was originally intended for submillimeter cerebral vein imaging without use of contrast agents, based on the fact that deoxygenated venous blood produces more magnetic field inhomogeneities than oxygenized arterial blood. Nevertheless, it was soon realized that the sensitivity of SWI of deoxygenated blood, as well as its sensitivity in detecting subtle susceptibility differences, allowed for many more imaging applications (106). In addition, with the new 3T scanners, SWI of the entire brain can be performed in less than 4 minutes (105). At present, most of the applications of SWI are in the field of neuroradiology, among which are TBI, hemorrhagic disorders, vascular malformations, cerebral infarctions, tumors, and neurodegenerative disorders associated with intracranial calcifications or iron deposition. When adding SWI sequences, in addition to diffusion-weighted and perfusion-weighted sequences, to the standard MR protocol, a more complete understanding of the disease process in question is accomplished, particularly when dealing with neurovascular and neurodegenerative disorders (105).

## USI of Muscle, Nerve, Connective Tissues, and Joints

USI involves the creation of visual images from the reflection of high-frequency mechanical waves back from different interfaces within the imaged tissues. Medical USI uses the ability of high-frequency sound to penetrate through multiple layers of tissue so that images can be constructed of the structures lying under the skin. Surfaces at which sound conductance changes generate an echo back to the transducer, depending on how much the sound conductance changes at the interface. Various different probes are available for USI. A transverse linear array probe is able to image from relatively flat surfaces and can be used to study soft tissues of the limbs or trunk. New machines that offer probe frequencies of up to 16 MHz offer the best-quality imaging of anatomic details for soft-tissue neuromusculoskeletal examination (Fig. 6-101).

## USI OF MUSCLE

The appearance of muscle with USI is determined by the complex interweaving of fibrous tissue and myocytes in the stromal architecture of the muscle. Reflections arise at interfaces between relatively dense fibrous tissue and relatively soft muscle tissue, where fibrous tissue wraps around individual muscle fascicles. In sagittal section, these fascicular interfaces form longitudinal striations along the length of the muscle. With an axial section of the muscle, the end-on view of the fascicular structure

**TABLE 6.1 A Comparison of MR Imaging Methods**

MR Method	Excitation–Emission Sequence	What Is Imaged?	Applications	Limitations
T1 weighted	TR: short (<1,000 ms) TE: short (<30 ms) Spin echo technique	T1 contrast. Fluid is dark. Fat is white. Brain parenchyma is gray. Tumor and edema are gray or dark. Ligament and tendon are dark. Methemoglobin (hemoglobin breakdown product >7 days) has high signal intensity.	Best spatial resolution for connective-tissue anatomy and bone marrow and trabecular anatomy. Myelin distribution and mucoid degeneration of tendons/menisci. Used for all post-contrast imaging—e.g., with gadolinium. Identify subacute to chronic hemorrhage.	Poor tissue edema contrast resolution. Poor sensitivity to pathologic lesions since most lesions involve increased tissue or edema fluid and T1 is not sensitive to the appearance of tissue fluid associated with acute inflammatory reaction or pathologic tissue changes.
T2 weighted	TR: long (>1,500 ms) TE: long (>60 ms) E.g., FSE technique	T2 contrast. Fluid is white. Fat is variable. Brain parenchyma is gray. Tumor and edema are white (hyperintense). Ligament and tendon are dark.	Regions with high free water content have high signal intensity—e.g., CSF, edema, nucleus pulposus, synovial fluid, abscess, and hyperacute hemorrhage (<1 day). Sensitive to pathologic appearance of fluid in parenchymal tissue.	Difficult-to-see high-intensity lesions adjacent to CSF or other free fluid regions—CSF has high signal intensity, as do T2 lesions; therefore tissue lesions at CSF interface are obscured.
STIR	TR: long (>4,000 ms) TE: short (<50 ms) TI: short values to null out fatty tissue	Very sensitive to tissue edema. Water content in soft tissue (e.g., nerve and muscle) produces a high signal intensity. Fat is suppressed.	MR neurography Muscle pathology imaging Pathologic fracture, bone edema, ligamentous or tendinous injury imaging	Poor spatial resolution but suitable to large body parts such as limbs and trunk or pelvis.
FLAIR	TR: long (e.g., 9,000 ms) TE: long (e.g., 130 ms) Heavily T2-weighted TI adjusted to null out free fluid signal (e.g., 2,200 ms)	Heavily T2-weighted with bulk water suppression, but without extracellular fluid/tissue edema suppression	White-matter T2 lesions seen more clearly than with T2-weighted Applied to MS, DAI/TBI, Lyme, HIV, brain infarction/ischemia	CSF pulsation artifact Blood flow artifact Requires careful adjustment of TI, especially when CSF is abnormal
MRA	Phase-contrast imaging; bipolar MFG.	Flowing spins	Blood flow; angiography. Noninvasive screening for cerebrovascular anomalies (e.g., cerebral aneurysms)	Longer study time Lower spatial resolution compared with x-ray angiography
DWI	EPIA; TR: long (e.g., 10,000 ms) Heavily T2-weighted. Phase-contrast imaging with large-amplitude bipolar MFGs Spin echo	Diffusing spins. To look at “restricted” or “anisotropic” diffusion, a diffusion “tensor” of directionally specific diffusion rates is computed for each voxel. DTI can be used to compute pathways of white fiber tracts (i.e., diffusion tensor tractography) and focal white-matter disruption	Ischemia; acute stroke; TBI; DAI. Held to be exquisitely and nearly immediately sensitive to the effects of ischemia on brain tissue due to focal reduction in diffusion of extracellular water in the ischemic region. H <sub>2</sub> O moves into intracellular space due to metabolic failure of ATP-dependent membrane-based Na-K pump Tissue perfusion assessment	Motion artifact; MR measurement cannot differentiate diffusion from local blood flow or tissue pulsation; T2-weighted due to long probe time. Can correct for effect of T2 weighting by calculating map of ADC values.

**TABLE 6.1 A Comparison of MR Imaging Methods (Continued)**

MR Method	Excitation–Emission Sequence	What Is Imaged?	Applications	Limitations
PWI	TR: short TE: short Images taken while contrast medium (e.g., gadolinium) power-injected intravenously at a fixed rate	Appearance of blood-conducted paramagnetic contrast medium in different brain regions		Involves dye injection using specialized equipment to control rate of infusion
fMRI—BOLD	EPIA; T2-weighted; Multiple image averaging to extract deoxyhemoglobin signal	Spatially localized tissue decrease in deoxyhemoglobin in regions of functionally related metabolic activation	Local tissue activation in functional brain activation/physiologic studies	Must average images to extract small deoxyhemoglobin signal Limited temporal resolution Subject must be cooperative and able to continuously perform the activation task

NOTE: The exact choices of parameter settings for TR, TE, and TI will vary according to the size of the static external magnetic field and various design details of the MR instrument.

ADC, apparent diffusion coefficient; DTI, diffusion tensor imaging; DWI, diffusion-weighted imaging; EPIA, echo planar image acquisition; FLAIR, fluid-attenuated inversion recovery; fMRI—BOLD, functional magnetic resonance imaging—blood-oxygen level-dependent technique; FSE, fast spin echo; MFG, magnetic field gradient; MRA, magnetic resonance angiography; PWI, perfusion-weighted imaging; STIR, short-tau inversion recovery; T1, longitudinal relaxation time (aka “spin-lattice relaxation time”—magnetization relaxation parallel to the static external magnetic field); T2, transverse relaxation time (aka “spin-spin relaxation time”—magnetization relaxation perpendicular to static external magnetic field—“precession”); TE, echo record time between RF pulse and signal recording window; TI, inversion recovery time; TR, repetition time between each new excitation–emission sequence.

produces a stippled cellular mosaic pattern (Fig. 6-102). The echogenicity of the muscle depends on the relative density of the fibrous matrix. In the presence of disuse atrophy, the echogenicity of the muscle increases as a result of volume loss in the myocytes and increased fibrofatty tissue content of the muscle. The normal bone surfaces are smooth and echogenic

**FIGURE 6-101.** MR diffusion-weighted image of an acute left middle cerebral artery stroke.

with posterior shadowing. The subcortical bone and underlying marrow are not evaluated with ultrasound, a disadvantage when compared to MRI. Tendons tend to be intermediate between bone and muscle in terms of echogenicity and have a dense nonpulsatile fibrillar pattern that helps to separate their appearance from vessels and nerves (107). Furthermore, they can be readily recognized by having the subject contract the muscle connected to the visualized tendon so that its active movement can be directly observed. This highlights one of the very unique and valuable features of USI: its ability to generate real-time images of structures that are dynamically active. The ultrasound image is constantly being updated on the screen at video rates to produce a “live-action” dynamic imaging of the tissue structure. Thus, it is possible to evaluate the relative motility of different structures and the “slide” that occurs at tissue interfaces as active and passive movement occurs during imaging. When a normal contracting muscle is imaged, the muscle can be seen to enlarge in cross section with irregular jerky motions seen within the muscle bulk. These appear to be contractions of individual fascicles during voluntary contraction of motor units. Fasciculations can be readily identified on real-time USI as a sudden isolated limited contraction within the muscle. USI allows for specific indications as to the intramuscular location of the motor unit generating the fasciculation. Also, dynamic USI can evaluate intrafascial or interfascial muscle herniation.

**FIGURE 6-102.** Normal biceps muscle on USI. The biceps muscle is labeled B and the humerus underneath it is labeled H. **A:** The axial image of the muscle. **B:** The sagittal image of the muscle. Note the normal striated structure in the two views.

### USI OF PERIPHERAL NERVE

USI can also be applied to the imaging of peripheral nerves. Nerves can have either an echogenic cross section when surrounded by relatively echolucent tissues or a relatively echolucent appearance in surrounding tissues that are relatively hyperechoic. With high-resolution USI, a stippled transverse cross-sectional appearance can be seen reflecting the fascicular internal structure of the nerve. Nerves can be differentiated from the three other major tubular structures: tendons/ligaments, arteries, and veins. Tendons/ligaments have well-defined anatomic locations, are densely hyperechoic, and can be made to move in a specific manner with appropriate patient movements. Arteries tend to pulsate regularly and veins collapse when compressed.

The median nerve can be readily identified in a transverse cross section of the wrist just proximal to the transverse carpal ligament. It lies just above the tendons of the flexor sublimis and deep to the palmaris tendon at this point and has a flattened oval appearance. In sagittal section, it is seen as a relatively echolucent structure with tendons above and below it. When the fingers are flexed, the flexor digitorum sublimis tendons can be seen moving back and forth under the static image of the nerve. In the axial transverse image, the nerve is normally very motile and changes its shape readily with wrist and finger motion. With full flexion of the fingers into the palm of the hand, the median nerve initially rises and then dives down into a deep pocket formed by the first sublimis tendon above, the flexor pollicis longus tendon medially and the first profundus tendon below. When the nerve becomes pathologically enlarged, some of this dynamic motion of the nerve is lost. It is also possible to generate images of the ulnar nerve as it passes around the elbow (Fig. 6-103).

In patients presenting with CTS, some changes are consistently noted on USI. Some doming of the flexor retinaculum may be present, reflecting a generalized enlargement of the contents of the tunnel. There may be some observable compression of the nerve, usually at the distal edge of the flexor retinaculum. The nerve appears less deformable with compression and

movement and may have increased blood flows associated with it, which can be detected with Doppler ultrasound. Finally, the nerve often is noted to be significantly enlarged (Fig. 6-104). The reason for this enlargement may be a combination of local edema, increased intrafascicular fibrous tissue development within the nerve (related to chronic inflammation), or a backup of axoplasmic fluid flow caused by compression. Furthermore, the nerve appears to be less mobile within the carpal segment, particularly with rapid repetitive motions of the wrist and fingers. USI can therefore provide some useful information about anatomic changes in the median nerve associated with CTS (Fig. 6-105). Imaging of the contents of the carpal tunnel can also detect other problems that could be contributing to CTS symptoms, such as nerve and ganglion cysts, synovial cysts, and osteophytes (108). USI has also been applied to the study of enlarged nerves in the hereditary motor

**FIGURE 6-103.** Longitudinal image of the ulnar nerve (arrows) proximal to the medial epicondyle. Note the striated appearance and homogeneous echotexture. High echogenic fat delineates the nerve.

**FIGURE 6-104.** Cross sectional sonographic images at the level of the carpal tunnel. **A:** Normal median nerve. **B:** There is diffuse enlargement to the median nerve with an area of  $0.370 \text{ cm}^2$ , well above the upper limits of normal ( $0.15 \text{ cm}^2$ ). and sensory neuropathies, to studies of ulnar nerve entrapment in the cubital tunnel, and to evaluation of the brachial plexus.

## USI OF JOINTS

Ultrasound is currently used for the evaluation of joint internal derangement. The shoulder, elbow, wrist, hip, knee, and ankle articulations are routinely evaluated with ultrasound for ligament, tendon, cartilage and fibrocartilage abnormalities. Current ultrasound technology allows imaging of structures not only during rest but also in real time during controlled limb movements, so that movement-dependent changes in anatomic relationship (e.g., shoulder impingement and snapping syndromes) can be visualized and evaluated. Different USI findings can be seen in muscle tear and rupture, tendon tear, tendonitis, ligament tears, and various soft-tissue overuse syndromes. Evaluation with USI, in the hands of a well-trained individual who understands the

underlying anatomy and pathophysiology, as well as the advantages and limitations of ultrasound technology, can be very helpful in the differential diagnosis of musculoskeletal complaints and the assessment of extent and severity of a musculoskeletal injury or condition. A detailed review of the application of musculoskeletal ultrasound is beyond the scope of this chapter, but interested readers are referred to available sources (109,110).

# Diagnostic Ultrasound

## INTRODUCTION

With recent advances in computer technology, equipment miniaturization, reduced cost, and ease of use, the clinical applications of diagnostic ultrasound (U/S) have spread across various medical specialties, including musculoskeletal medicine. In this chapter, we review several common pathologies of the shoulder, the elbow, and the knee to demonstrate the utility of diagnostic U/S in musculoskeletal medicine. Detailed procedures for examining the upper and lower extremities have been described in two recent publications (1,2) and are only briefly mentioned in this chapter.

Two major imaging modalities for detection of soft tissue injuries are magnetic resonance imaging (MRI) and (U/S). Musculoskeletal U/S is, by no means, a replacement of MRI. Instead, it should be viewed as an extension of our physical examination. Typically, MRI can reveal static features of muscles, tendons, nerves, and bones. However, when compared with U/S, the disadvantages of MRI are (a) its limited accessibility in the clinic, (b) longer examination time, and (c) higher cost. On the other hand, modern musculoskeletal U/S can provide high-resolution and real-time imaging of the nerves, tendons, muscles, and joint recesses, provided that the structures are not too deep or obscured by hyperechoic body parts (3).

Musculoskeletal U/S plays a role not only in the assessment of soft tissue pathologies but also as an adjunct to a number of common interventional procedures. When used appropriately, U/S guidance improves the accuracy of steroid injection into joint cavities, bursa, and tendon sheaths, thus improving its therapeutic efficacy (4,5) and thereby reducing the risk of iatrogenic complications. By the same token, the application of U/S for regional nerve blocks is also gaining popularity (6,7). In a recent study, ultrasonography has been successfully used to locate the sacral hiatus for caudal epidural injections (8). Moreover, U/S-guided sacroiliac joint injection, facet joint injection, and medial branch block have been advocated as viable options over fluoroscopy- and computed tomography-guided techniques (9–11).

U/S images vary with the reflection of the U/S waves, the amount of which defines the echogenicity. Thus, common terms used to describe the anatomic structures in the areas of interest include “hyperechoic,” “isoechoic,” “hypoechoic,” and “anechoic.” In ultrasonography reports, the images are also described in terms of the plane with which the scanning

was performed, either longitudinal or transverse. Typically, a linear array probe is used in musculoskeletal examination, as its wider view and higher near-field resolution provide good images of superficial structures. Figure 7-1 shows an example of a U/S machine and the transducer probes. The degree of U/S penetration also depends on its frequency. Probes with higher frequency ranges (7 to 12 MHz) are commonly used to assess very superficial structures. Probes with lower frequency ranges (5 to 7.5 Hz) are often used to assess structures that are deeper, since they allow greater tissue penetration (3). In addition, power Doppler, a technique that takes into account the amount of red blood cells being scanned, can be used to indirectly demonstrate blood flow within the scanned area. In the three sections below, we review the imaging of several common musculoskeletal pathologies, (a) the shoulder, (b) the elbow, and (c) the knee.

## EXAMPLES OF SHOULDER PATHOLOGY

### Supraspinatus Tendon Tear

Supraspinatus tendon tears are commonly seen in individuals participating in sports such as baseball, tennis, or swimming. Pain on resisted shoulder abduction suggests pathology of the supraspinatus tendon. On longitudinal scan, a normal supraspinatus tendon should appear as a beak-shaped, echogenic fibrillar structure extending under the acromion, between the humeral head and the subacromial/subdeltoid bursa. On transverse scan, the tendon appears as a band of medium-level echogenic structures, deep to the subdeltoid bursa and superficial to the hypoechoic hyaline cartilage on the humeral head. A partial-thickness tear is demonstrated as a focal anechoic lesion (Fig. 7-2A) or as a mixed “hyperechoic and hypoechoic” focus in the poorly vascularized critical zone of the supraspinatus tendon. The main sonographic features of a full-thickness tear (Fig. 7-2B) include focal nonvisualization through the width of the tendon, as demonstrated in the transverse view (12).

There is inherent interobserver variability in the detection and characterization of supraspinatus tendon tears (12,13). However, with standardized diagnostic criteria, high-quality scanning equipment, and well-trained sonographers, several studies have reported sensitivities and specificities exceeding 90% in the detection of full- and partial-thickness rotator cuff tears (14–16).

**FIGURE 7-1.** Basic instrumentation. An example of a diagnostic U/S machine (**left**) and the transducer probes (**right**). U/S images are generated when pulses of U/S from the transducer produce echoes at tissue or organ boundaries. Between pulse transmissions, the transducer serves as a detector of echoes, which are processed to form an anatomic image.

A

B

**FIGURE 7-2.** Supraspinatus tendon tear. **A:** A longitudinal scan of supraspinatus tendon (SS) with a partial-thickness tear reveals an anechoic defect (*white arrow*) inside the tendon. **B:** A transverse scan of SS with a full-thickness tear reveals a sonoluent defect inside the tendon and a hyperechoic line (*white arrow*) between the defect and the hypoechoic cartilage of the humeral head (cartilage interface sign).

**FIGURE 7-3.** Subacromial-subdeltoid bursitis. **A:** Scanning parallel to the axis of the supraspinatus tendon (SUP) and lateral to the greater tuberosity (GT) reveals a typical “teardrop” shape of bursal effusion (*white arrows*), with bursal wall thickening. **B:** Scanning parallel to the axis of the subscapular tendon (SUB) reveals distension of the bursa (*white arrows*), with irregular synovial thickening. DEL, deltoid muscle; LT, lesser tuberosity of humeral head.

### Subacromial-Subdeltoid Bursitis

Subacromial-subdeltoid bursitis is often associated with repeated trauma; and in middle-aged or older individuals, it tends to be linked with overuse or degenerative changes in the rotator cuff (17). A normal bursa should appear on U/S as a thin hypoechoic stripe, covered by a narrow layer of echogenic peribursal fat, located between the underlying supraspinatus tendon and the overlying deltoid muscle. Typically, it is less than 2 mm in thickness, even counting the hypoechoic layer of fluid located between the two sides of the bursa (18).

A small effusion in the subacromial/subdeltoid bursa may be identified lateral to the greater tuberosity, especially with the arm extended and internally rotated (Fig. 7-3A). The examiner should be careful not to compress and displace the small amount of fluid. Fluid accumulation within the subacromial/subdeltoid bursa is often noted in patients with infectious or inflammatory bursitis (Fig. 7-3B). However, it can also be observed in patients with full-thickness tear of rotator cuff tendon or in individuals with shoulder impingement syndrome (19). If a needle intervention is deemed necessary, U/S can be utilized to guide bursal fluid aspiration or steroid injection (20).

### Bicipital Tenosynovitis

Bicipital tenosynovitis is an inflammation of the long head of the biceps where the tendon passes through the bicipital groove. When the biceps tendon is inflamed, local tenderness in the bicipital groove and an increasing painful arc (painful sensation when the shoulder is flexed from 30 to 120 degrees) are often present. When a clinician is uncertain about the accuracy of the Yergason’s supination test or Speed’s test (21,22), he or she may consider the use of U/S to improve its diagnosis and treatment.

The long head of the biceps brachii originates at the supraglenoid tubercle and glenoid labrum in the most superior portion of the glenoid. It lies in the bony groove between the greater tuberosity and the lesser tuberosity of the humeral head. The transverse bicipital ligament keeps the tendon confined within the groove. On transverse scan, with the arm in neutral position, the long head of biceps tendon of a normal subject is visualized as an oval-shaped, echogenic structure within the bicipital groove. In ultrasonography, the tendon is typically seen as an array of echogenic fibrillar lines, emerging from beneath the acromion and traversing distally to the musculoskeletal junction, where it becomes indistinguishable from the muscle belly.

In biceps tendonitis, effusion in the tendon sheath is associated with focal tenderness and often with heterogeneity of the tendon (Fig. 7-4A,B). Bicipital sheath fluid accumulation indicates intra-articular pathology rather than biceps tendon pathology per se, because of the connection of the sheath with the glenohumeral joint (23). Thus, bicipital sheath effusion may also be seen in supraspinatus tendon tear (24).

## EXAMPLES OF ELBOW PATHOLOGY

### Lateral Epicondylitis

Lateral epicondylitis is usually caused by repetitive traction of the common extensor tendon (CET) at its osteotendinous attachment to the lateral humeral epicondyle (27). Diagnosis is usually made clinically, without any need for imaging. U/S provides direct visualization of the CET for both the patient and the clinician and can provide confirmatory signs in the

**FIGURE 7-4.** Biceps tendinitis. **A:** A transverse scan at the level of the bicipital groove shows anechoic fluid (*white arrow*) accumulation surrounding a tender, thickened biceps tendon in a patient with biceps tenosynovitis. **B:** On longitudinal scan, fluid accumulation (*white arrow*) around the tendon is noted.

evaluation process (25,26). In the longitudinal view via U/S examination, the CET should appear as an echogenic beak-shaped structure (Fig. 7-5A). Main U/S features of a “tennis elbow” may include swelling of the tendon, partial tear,

calcification, and hyperemia. In Figure 7-5B, the diffuse, thickened hypoechoic area with loss of normal fibrillar pattern is compatible with tendinopathy. A focal anechoic area on ultrasonography indicates a complete or partial rupture of the

**FIGURE 7-5.** Lateral epicondylitis. **A:** Normal sonographic image of the lateral elbow. The CET (T) presents as an echogenic beak-shaped structure, while the extensor muscle (EM) is relatively hypoechoic. LE, lateral epicondyle; RH, radial head. **B:** Swelling of the tendon is seen as hypoechoic thickening with loss of normal fibrillar pattern (between the *arrowheads*) near its insertion. **C:** Linear shape calcification (*arrows*) is seen inside the tendon. **D:** Power Doppler indicates a hypervascular status inside the tendon (*arrows*). This is frequently seen in an actively inflamed tendon.

**FIGURE 7-6.** UCL tear. The anterior band of UCL is seen on U/S as having two components, the superficial component (between “++”) and the deep component (between “xx”). ME, medial epicondyle; CP, coronoid process; FM, flexor muscle.

CET, which may require surgical intervention. As expected, calcification of the tendon can be seen as echogenic foci within the CET with or without acoustic shadow beneath the lesion (Fig. 7-5C). Cystic lesions can occasionally be seen around the CET. With power Doppler imaging, hypervascularity of the CET (Fig. 7-5D) is suggestive of focal hyperemia and active inflammation.

### Ulnar Collateral Ligament Rupture

An ulnar collateral ligament (UCL) tear may result from either acute or chronic valgus stress to the elbow. Repeated overhead throwing or pitching is a common cause of UCL injury (28,29). Traditionally, MRI has been used for assessment of UCL injury. However, U/S not only can visualize the UCL in a static view (Fig. 7-6) but also can evaluate the related structures during motion. A dynamic U/S study can assess joint laxity by comparing the degree of joint widening of both arms during valgus stress. Both U/S and MRI have been used to assess UCL injury, and their diagnostic accuracies are quite comparable (30). In another study, 26 asymptomatic major league professional baseball pitchers were assessed by U/S. When compared to the non-pitching arms, the pitching arms were found to have thicker UCL anterior bands and wider joint spaces (31).

## EXAMPLES OF KNEE PATHOLOGY

### Knee Effusion

For U/S detection of knee effusion, it is best to place the patient in a supine position, with a pillow below the knee, and the knee either extended or slightly bent. The transducer is placed longitudinally along the axis of quadriceps tendon (Fig. 7-7A). The suprapatellar recess is located between the quadriceps tendon and the prefemoral fat (Fig. 7-7B). The normal suprapatellar recess is slit-like, with the thickness no more than 2 mm (32). Knee effusion is demonstrated as a distended suprapatellar recess with anechoic space (Fig. 7-7C),

which is easily compressed, and without vascularity on power Doppler imaging. In repeated injuries, synovium hypertrophy can occur within the suprapatellar recess. The enlarged synovium often appears as a hyperechoic mass, either attached to the wall of the suprapatellar recess or floating within it (Fig. 7-7D). As in other scenarios, increased synovial vascularity indicates active inflammation. If a large amount of effusion is noted after an injury, one should suspect internal knee derangement, which may be better diagnosed with MRI and arthroscopy (33).

### Patellar Tendonitis

Patients with patellar tendinitis (also known as “jumper knee”) may complain of anterior knee pain while jumping or going down stairs. Local tenderness over the patellar tendon is a common manifestation. When scanning the patellar tendon, the patient should be placed in supine position, with the patellar tendon tightened by flexing the knee to 60 to 80 degrees (Fig. 7-8A). The normal longitudinal patellar tendon should appear as parallel, fibrillar, echogenic structures (Fig. 7-8B). Commonly observed sonographic findings of patellar tendinitis include loss of fibrillar pattern, reduced echogenicity, and tendon hypertrophy in comparison with the contralateral knee (33). This is demonstrated in Figure 7-8C. Increased vascularity on power Doppler examination (Fig. 7-8D) suggests an acute inflammatory process. Studies have also shown that the presence of abnormal sonographic findings in the patellar tendon, even in the absence of subjective symptomatology, is associated with the higher risk of future patellar tendon injury (34).

### Muscular Injury

Muscular injury is quite common in athletes. It may result from direct trauma or may sometimes be caused by overstretching, especially with insufficient warm-up. On U/S, normal muscle should appear as feather-like, longitudinal fibrils. Muscle tear will manifest as a disruption of muscular fibrils. An anechoic area within an injured muscle suggests hematoma

**FIGURE 7-7.** Knee effusion. **A:** Examination of knee effusion: transducer is aligned along the quadriceps tendon. **B:** Normal suprapatellar recess (between markers) is slit-like, located between the quadriceps (Q) tendon and prefemoral fat (PF). **C:** Effusion of knee demonstrates itself as a distended anechoic mass, which is easily compressed. **D:** Hyperechoic villus is seen floating within the suprapatellar recess.

or effusion (Fig. 7-9A). On U/S, the severity of muscle injury can be divided into three grades. In grade I injury, no obvious muscular fibril rupture is observed, indicating a minor injury. Echogenicity of the injured muscle may be reduced due to swelling or bleeding. In grade II injury, fibrillar tear can be observed, with disruption of the normal muscular texture. An anechoic area due to either local hematoma or effusion is often apparent. Sometimes, the ruptured end of muscular fibril floats within the local effusion and is referred to as the “bell clapper sign.” In grade III injury, the muscle tear is unfortunately complete. The round end of the ruptured “stump” can be seen, and the muscle gap will widen during stretching. An example of a complete quadriceps tear is seen in Figure 7-9B.

### Posterior Cruciate Ligament Injury

Unlike the anterior cruciate ligament, the posterior cruciate ligament (PCL) can be clearly visualized on U/S examination (35). When scanning the PCL, the patient should be placed in prone position, with the knee extended. The transducer is located between the lateral margin of the medial femoral

condyle and the midportion of the tibial intercondylar (Fig. 7-10A). The normal PCL should appear as a hypoechoic, fan-shaped structure (Fig. 7-10B). Rupture is suspected when the thickness of PCL at the tibial spine is greater than 10 mm and with a waxy posterior margin (36) (Fig. 7-10C,D).

The above-mentioned examples present a limited selection of common musculoskeletal pathologies encountered by practicing physiatrists. Together they serve as a brief introduction of the clinical applications of musculoskeletal U/S. There are numerous other conditions that U/S can be used for diagnostic, therapeutic, and research purposes, such as for evaluation of the median nerve in carpal tunnel syndrome (37,38). The integrity of ankle ligaments and tendons can also be evaluated with U/S (39,40). Moreover, U/S characteristics of plantar fasciitis have been well established, and injection of steroid under U/S guidance had been shown to be effective (41). There are many other applications of U/S that are beyond the scope of this chapter. Readers are encouraged to refer to musculoskeletal U/S textbooks for more thorough descriptions (42).

**FIGURE 7-8.** Patellar tendinitis. **A:** Examination of patellar tendon: the knee is flexed to 60 to 80 degrees to stretch the patellar tendon. **B:** Normal sonogram of patellar tendon shows the typical hyperechoic fibrillar pattern. **C:** Sonogram of patellar tendon tendinopathy reveals reduced echogenicity and increased thickness. **D:** Increased vascularity of patellar tendon is revealed, indicating active inflammation of the patellar tendon.

**FIGURE 7-9.** Muscle tear. **A:** Anechoic gap is seen within the quadriceps tendon, representing a tear. The round end of the ruptured muscle is well-defined on sonogram (arrows). **B:** A wider view of the ruptured quadriceps muscle reveals the extent of the injury.

**FIGURE 7-10.** PCL injury. **A:** The patient is in prone position, with knee extended. The transducer is aligned between the lateral margin of the medial condyle and the intercondylar region of the femur. **B:** The PCL reveals itself as fan-like hypoechoic band due to anisotropy (arrow). **C:** U/S shows PCL tear and thickening. **D:** A waxy posterior margin of PCL is seen.

## CONCLUSION

The ability to perform dynamic examinations with real-time visualization and rapid side-to-side comparisons makes U/S eminently suitable for the diagnosis of musculoskeletal pathologies. In addition to assisting with initial diagnosis, U/S images can also be used in guiding needle injections and in quantifying the recovery process. While helpful, musculoskeletal U/S is, by no means, a replacement for other diagnostic methods such as MRI and arthroscopy. Instead, it should be viewed as an extension of our physical examination.

Limitations of U/S include its dependence on the experience of the operator and a relatively long learning curve. Adequate training and supervision may minimize these limitations; however, training opportunities and certification for musculoskeletal U/S are currently not standardized. The paucity of widely accepted standard examination protocols accentuates the variability of results attributable to operator dependence. Despite these limitations, U/S, when used appropriately, provides an important adjunct to physical examination to aid in the diagnosis and thus in the treatment of common musculoskeletal pathologies.

# Principles and Applications of Measurement Methods

Objective measurement provides a scientific basis for communication between professionals, documentation of treatment efficacy, and scientific credibility within the medical community. Federal, state, private third-party payer, and consumer organizations increasingly are requiring objective evidence of improvement as an outcome of treatment. Empirical clinical observation is no longer an acceptable method without objective data to support clinical decision making. The lack of reliability of clinicians' unaided measurement capabilities is documented in the literature (1–7), further supporting the importance of objective measures. In addition, comparison of alternative evaluation or treatment methods, when more than one possible choice is available, requires appropriate use of measurement principles (8–11).

Clinicians and clinical researchers use measurements to assess characteristics, functions, or behaviors thought to be present or absent in specific groups of people. The application of objective measures uses structured observations to compare performances or characteristics across individuals (i.e., to discriminate), or within individuals over time (i.e., to evaluate), or for prognostication based on current status (i.e., to predict) (12,13). It is important to understand the principles of measurement and the characteristics of good measures to be an effective user of the tools. Standards for implementation of tests and measures have been established within physical therapy (14,15), psychology (16), and medical rehabilitation (17) to address quality improvement and ethical issues for the use of clinical measures.

The purpose of this chapter is to discuss the basic principles of tests and measurements and to provide the reader with an understanding of the rationale for assessing and selecting measures that will provide the information required to interpret test results properly. A standardized test is a test administered and scored in a consistent manner. The tests are designed in such a way that the questions, conditions for administering, scoring procedures, and interpretations are consistent and are administered and scored in a predetermined, standard manner. A critical starting point is to define what is to be measured, for what purpose, and at what cost. Standardized measurements meeting these criteria should then be assessed for reliability and validity pertinent to answering the question or questions posed by the user. Measurements that are shown not to be valid

or reliable provide misleading information that is ultimately useless (18).

The initial section of this chapter discusses the psychometric parameters used to evaluate tests and measures. Principles of evaluation, testing, and interpretation are detailed in the second section. The fourth section provides guidelines for objective measurement when a standardized test is not available to measure the behavior, function, or characteristic of interest.

The complexity and diversity of the tests and measures used in rehabilitation medicine clinical practice and research preclude itemized description in a single chapter. A prerequisite for a measure to be objective requires that adequate levels of reliability have been demonstrated (18). Measures that have acceptable levels of reliability must also be shown to have appropriate types of validity to ultimately be labeled as objective. It is, therefore, imperative that the user be able to recognize the limitations of tests he or she employs to avoid inadvertent misuse or misinterpretation of test results.

## PSYCHOMETRIC PARAMETERS USED TO EVALUATE TESTS AND MEASURES

The methods developed primarily in the psychology literature to evaluate objective measures generally are applicable to the standardized tests and instruments used in rehabilitation medicine. The topics discussed in this section are the foundation for all useful measures. Measurement tools must have defined levels of measurements for the trait or traits to be assessed and a purpose for obtaining the measurements. Additionally, tests and measures need to be practical, reliable, and valid.

### Levels of Measurement

Tests and measures come in multiple forms because of the variety of parameters measured in clinical practice and research.

Despite the seemingly overwhelming number of measures, there are classified levels of measurement that determine how test results should be analyzed and interpreted (19). The four basic levels of measurement data are nominal, ordinal, interval, and ratio. Nominal and ordinal scales are used to classify discrete measures because the scores produced fall into discrete categories. Interval and ratio scales are used to classify continuous

measures because the scores produced can fall anywhere along a continuum within the range of possible scores.

A nominal scale is used to classify data that do not have a rank order. The purpose of a nominal scale is to categorize people or objects into different groups based on a specific variable. An example of nominal data is diagnosis.

Ordinal data are operationally defined to assign individuals to categories that are mutually exclusive and discrete. The categories have a logical hierarchy, but it cannot be assumed that the intervals are equal between each category, even if the scale appears to have equal increments. Ordinal scales are the most commonly used level of measurement in clinical practice. Examples of ordinal scales are the manual muscle test scale (20–24) and functional outcome measures (e.g., functional independence measure [FIM]) (25).

Interval data, unlike nominal and ordinal scales, are continuous. An interval scale has sequential units with numerically equal distances between them. Interval data often are generated from quantitative instrumentation as opposed to clinical observation. It is important to note that it is statistically possible to transform ordinal data into interval data using Rasch logit scale methods. This has most notably been utilized in medical rehabilitation for analysis of FIM data. Detailed information regarding how to perform this transformation can be found elsewhere (26).

Examples of interval measurements are range-of-motion scores reported in degrees and the visual analogue pain scale (continuum from 0 to 10).

A ratio scale is an interval scale on which the zero point represents a total absence of the quantity being measured. An example is force scores obtained from a quantitative muscle strength-testing device.

Analysis of nominal and ordinal scales requires special consideration to avoid misinference from test results (27,28). The major controversies surrounding the use of these scales are the problems of unidimensionality and whether scores of items and subtests can be summed to provide an overall score. Continuous scales have a higher sensitivity of measurement and allow more rigorous statistical analyses to be performed. Sensitivity can be defined as the proportion of people with a condition/trait who test positive for that condition/trait.

## Purpose of Testing

After the level of the measurement has been selected, the purpose of testing must be examined. Tests generally serve one of two purposes: screening or in-depth assessment of specific traits, behaviors, functions, or prognosis.

## Screening Tests

Screening tests have three possible applications:

1. To discriminate between “suspect” and “normal” patients
2. To identify people needing further assessment
3. To assess a number of broad categories superficially

One example of a screening test is the Test of Orientation for Rehabilitation Patients, administered to individuals who are

confused or disoriented secondary to traumatic brain injury, cerebrovascular accident, seizure disorder, brain tumor, or other neurologic events (29–32). This test screens for orientation to person and personal situation, place, time, schedule, and temporal continuity. Another well-developed screening test is the Miller Assessment for Preschoolers (MAP) (33). This test screens preschoolers for problems in the following areas: sensory and motor, speech and language, cognition, behaviors, and visual-motor integration.

The advantages of screening tests are that they are brief and sample a broad range of behaviors, traits, or characteristics. They are limited, however, because of an increased frequency of false-positive results that is due to the small sample of behaviors obtained. Screening tests should be used cautiously for diagnosis, placement, or treatment planning. They are used most effectively to indicate the need for more extensive testing and treatment of specific problem areas identified by the screening assessment.

## Assessment Tests

Assessment tests have five possible applications:

1. To evaluate specific behaviors in greater depth
2. To provide information for planning interventions
3. To determine placement into specialized programs
4. To provide measurements to monitor progress
5. To provide information regarding prognosis

An example of an assessment measure is the Boston Diagnostic Aphasia Examination (34). The advantages of assessment measures are that they have a lower frequency of false-positive results; they assess a representative set of behaviors; they can be used for diagnosis, placement, or treatment planning; and they provide information regarding the functional level of the individual tested. The limitations are that an extended amount of time is needed for testing, and they generally require specially trained personnel to administer, score, and interpret the results.

## Criterion-Referenced Versus Norm-Referenced Tests

Proper interpretation of test results requires comparison with a set of standards or expectations for performance. There are two basic types of standardized measures: criterion-referenced and norm-referenced tests.

## Criterion-Referenced Tests

Criterion-referenced tests are those for which the test score is interpreted in terms of performance on the test relative to the continuum of possible scores attainable (18). The focus is on what the person can do or what he or she knows rather than how he or she compares with others (35). Individual performance is compared with a fixed expected standard rather than a reference group. Scores are interpreted based on absolute criteria, for example, the total number of items successfully completed. Criterion-referenced tests are useful to discriminate between successive performances of one person. They are

conducted to measure a specific set of behavioral objectives. The Tufts Assessment of Motor Performance (which has undergone further validation work and has been renamed the Michigan Modified Performance Assessment) is an example of a criterion-referenced test (36–40). This assessment battery measures a broad range of physical skills in the areas of mobility, activities of daily living, and physical aspects of communication.

### Norm-Referenced Tests

Norm-referenced tests use a representative sample of people who are measured relative to a variable of interest. Norm referencing permits comparison of a single person's measurement with those scores expected for the rest of the population. The normal values reported should be obtained from, and reported for, clearly described populations. The normal population should be the same as those for whom the test was designed to detect abnormalities (35). Reports of norm-referenced test results should use scoring procedures that reflect the person's position relative to the normal distribution (e.g., percentiles, standard scores). Measures of central tendency (e.g., mean, median, mode) and variability (e.g., standard deviation, standard error of the mean) also should be reported to provide information on the range of normal scores, assisting with determination of the clinical relevance of test results. An example of a norm-referenced test is the Peabody Developmental Motor Scale (41). This developmental test assesses fine and gross motor domains. Test items are classified into the following categories: grasp, hand use, eye-hand coordination, manual dexterity, reflexes, balance, nonlocomotor, locomotor, and receipt and propulsion of objects.

### Practicality

A test or instrument should ideally be practical, easy to use, insensitive to outside influences, inexpensive, and designed to allow efficient administration (42). For example, it is not efficient to begin testing in a supine position, switch to a prone position, and then return to supine. Test administration should be organized to complete all testing in one position before switching to another. Instructions for administering the test should be clear and concise, and scoring criteria should be clearly defined. If equipment is required, it must be durable and of good quality. Qualifications of the tester and additional training required to become proficient in test administration should be specified. The time to administer the test should be indicated in the test manual. The duration of the test and level of difficulty need to be appropriate relative to the attention span and perceived capabilities of the patient being tested. Finally, the test manual should provide summary statistics and detailed guidelines for appropriate use and interpretation of test scores based on the method of test development.

### Reliability and Agreement

A general definition of reliability is the extent to which a measurement provides consistent information (i.e., is free from random error). Granger et al. (43) provide the analogy “it may be thought of as the extent to which the data contain relevant

information with a high signal-to-noise ratio versus irrelevant static confusion.” By contrast, agreement is defined as the extent to which identical measurements are made. Reliability and agreement are distinctly different concepts and are estimated using different statistical techniques (44). Unfortunately, these concepts and their respective statistics often are treated synonymously in the literature.

The level of reliability is not necessarily congruent with the degree of agreement. It is possible for ratings to cluster consistently toward the same end of the scale, resulting in high-reliability coefficients, and yet these judgments may or may not be equivalent. High reliability does not indicate whether the raters absolutely agree. It can occur concurrently with low agreement when each rater scores patients differently, but the relative differences in the scores are consistent for all patients rated. Conversely, low reliability does not necessarily indicate that raters disagree. Low-reliability coefficients can occur with high agreement when the range of scores assigned by the raters is restricted or when the variability of the ratings is small (i.e., in a homogeneous population). In instances in which the scores are fairly homogeneous, reliability coefficients lack the power to detect relationships and are often depressed, even though agreement between ratings may be relatively high. The reader is referred to Tinsley and Weiss for examples of these concepts (45). Both reliability and agreement must be established on the target population or populations to which the measure will be applied, using typical examiners. There are five types of reliability and agreement:

1. Interrater
2. Test-retest
3. Intertrial
4. Alternate form
5. Population specific

Each type will be discussed below, along with indications for calculating reliability versus agreement and their respective statistics.

### Interrater Reliability and Agreement

Interrater or interobserver agreement is the extent to which independent examiners agree exactly on a patient's performance. By contrast, interrater reliability is defined as the degree to which the ratings of different observers are proportional when expressed as deviations from their means; that is, the relationship of one rated person to other rated people is the same, although the absolute numbers used to express the relationship may vary from rater to rater (45). The independence of the examiners in the training they receive and the observations they make is critical in determining interrater agreement and reliability. When examiners have trained together or confer when performing a test, the interrater reliability or agreement coefficient calculated from their observations may be artificially inflated.

An interrater agreement or reliability coefficient provides an estimate of how much measurement error can be expected in scores obtained by two or more examiners who have

independently rated the same person. Determining interrater agreement or reliability is particularly important for test scores that largely depend on the examiner's skill or judgment. An acceptable level of interrater reliability or agreement is essential for comparison of test results obtained from different clinical centers. Interrater agreement or reliability is a basic criterion for a measure to be called objective. If multiple examiners consistently obtain the same absolute or relative scores, then it is much more likely that the score is a function of the measure, rather than of the collective subjective bias of the examiners (18).

Pure interrater agreement and reliability are determined by having one examiner administer the test while the other examiner or examiners observe and independently score the person's performance at the same point in time. When assessing some parameters, when the skill of the examiner administering the test plays a vital role (e.g., sensory testing, range-of-motion testing) or when direct observation of each examiner is required (e.g., strength), it is impossible to assess pure interrater agreement and reliability. In these instances, each examiner must test the individual independently. Consequently, these interrater measures are confounded by factors of time and variation in patient performance.

### Test-Retest Reliability and Agreement

Test-retest agreement is defined as the extent to which a patient receives identical scores during two different test sessions when rated by the same examiner. By contrast, test-retest reliability assesses the degree of consistency in how a person's score is rank ordered relative to other people tested by the same examiner during different test sessions. Test-retest reliability is the most basic and essential form of reliability. It provides an estimate of the variation in patient performance on a different test day, when retested by the same examiner. Some of the errors in a test-retest situation also may be attributed to variations in the examiner's performance. It is important to determine the magnitude of day-to-day fluctuations in performance so that true changes in the parameters of interest can be determined. Variability of the test or how it is administered should not be the source of observed changes over time. Additionally, with quantitative measuring instruments, the examiner must be knowledgeable in the method of and frequency required for instrument calibration.

The suggested test-retest interval is 1 to 3 days for most physical measures and 7 days for maximal effort tests in which muscle fatigue is involved (46). The test-retest interval should not exceed the expected time for change to occur naturally. The purpose of an adequate but relatively short interval is to minimize the effects of memory, practice, and maturation or deterioration on test performance (47).

### Intertrial Reliability and Agreement

Intertrial agreement provides an estimate of the stability of repeated scores obtained by one examiner within a test session. Intertrial reliability assesses the consistency of one examiner

rank-ordering repeated trials obtained from patients using the same measurement tool and standardized method for testing and scoring results within a test session. Intertrial agreement and reliability also are influenced by individual performance factors such as fatigue, motor learning, motivation, and consistency of effort. Intertrial agreement and reliability should not be confused with test-retest agreement and reliability. The latter involves test sessions usually separated by days or weeks as opposed to seconds or minutes for intertrial agreement and reliability. A higher level of association is expected for results obtained from trials within a test session than those from different sessions.

### Alternate Form Reliability and Agreement

Alternate form agreement refers to the consistency of scores obtained from two forms of the same test. Equivalent or parallel forms are different test versions intended to measure the same traits at a comparable level of difficulty. Alternate form reliability refers to whether the parallel forms of a test rank order people's scores consistently relative to each other. A high level of alternate form agreement or reliability may be required if a person must be tested more than once and a learning or practice effect is expected. This is particularly important when one form of the test will be used as a pretest and a second as a posttest.

### Population-Specific Reliability and Agreement

Population-specific agreement and reliability assess the degree of absolute and relative reproducibility, respectively, that a test has for a specific group being measured (e.g., Ashworth scale scores for rating severity of spasticity from spinal cord injury). A variation of this type of agreement and reliability refers to the population of examiners administering the test (18).

### Interpretation of Reliability and Agreement Statistics

Because measures of reliability and agreement are concerned with the degree of consistency or concordance between two or more independently derived sets of scores, they can be expressed in terms of correlation coefficients (35). The reliability coefficient is usually expressed as a value between 0 and 1, with higher values indicating higher reliability. Agreement statistics can range from  $-1$  to  $+1$ , with  $+1$  indicating perfect agreement, 0 indicating chance agreement, and negative values indicating less than chance agreement. The coefficient of choice varies, depending on the data type analyzed. The reader is referred to Bartko and Carpenter (48), Hartmann (49), Hollenbeck (50), Liebetrau (51), and Tinsley and Weiss (45) for discussions of how to select appropriate statistical measures of reliability and agreement. Table 8-1 provides information on appropriate statistical procedures for calculating interrater and test-retest reliability and agreement for discrete and continuous data types. No definitive standards for minimum acceptable levels of the different types of reliability and agreement statistics have been established; however, guidelines for minimum levels are

**TABLE 8.1** Interrater Reliability, Test-Retest Reliability, and Agreement Analysis: Appropriate Statistics and Minimum Acceptable Levels

Data Type	Reliability Analysis		Agreement Analysis	
	Appropriate Statistic	Level	Appropriate Statistic	Level
Discrete				
Nominal	ICC or $\kappa_w$	>0.75	$\kappa$	>0.60
Ordinal	ICC	>0.75	$\kappa_w$	>0.60
Continuous				
Interval	ICC	>0.75	$\chi^2$ and $T$	$P < 0.05$
Ratio	ICC	>0.75	$\chi^2$ and $T$	$P < 0.05$

References: ICC: discrete (47,55), ordinal (47), continuous (44,47), minimal acceptable level (56); Cohen's  $\kappa$ — $\kappa$  (44,47,57,58),  $\kappa_w$  (47,59,60),  $\kappa_w$  equivalence with ICC for reliability analysis of minimal data (61–64), minimal acceptable level (65); Lawlis and Lu's  $\chi^2$  and  $T$ ; statistical and minimal level (43,44).  
ICC, intraclass correlation;  $\kappa$ , kappa;  $\kappa_w$ , weighted kappa;  $T$ ,  $T$  index.

provided in Table 8-1. The acceptable level varies, depending on the magnitude of the decision being made, the population variance, the sources of error variance, and the measurement technique (e.g., instrumentation vs. behavioral assessments). If the population variance is relatively homogeneous, lower estimates of reliability are acceptable. By contrast, if the population variance is heterogeneous, higher estimates of reliability are expected. Critical values of correlation coefficients, based on the desired level of significance and the number of subjects, are provided in tables in measurement textbooks (52,53). It is important to note that a correlation coefficient that is statistically significant does not necessarily indicate that adequate reliability or agreement has been established, because the significance level only provides an indication that the coefficient is significantly different from zero (see Table 8-1).

Agreement and reliability both are important for evaluating patient ratings. As discussed earlier, these are distinctly different concepts and require separate statistical analysis. Several factors must be considered to determine the relative importance of each. Decisions that carry greater weight or impact for the people being assessed may require more exact agreement. If the primary need is to assess the relative consistency between raters, and exact agreement is less critical, then a reliability measure alone is a satisfactory index. By contrast, whenever the major interest is either the absolute value of the score or the meaning of the scores as defined by the points on the scale (e.g., criterion-referenced tests), agreement should be reported in addition to the reliability (45). Scores generated from instrumentation are expected to have a higher level of reliability or agreement than scores obtained from behavioral observations.

A test score actually consists of two different components: the true score and the error score (35,54). A person's true score is a hypothetical construct, indicating a test score that is unaffected by chance factors. The error score refers to the unwanted variation in the test score (55). All continuous scale measurements have a component of error, and no test is completely reliable. Consequently, reliability is a matter of degree. Any reliability coefficient may be interpreted directly in terms of percentage of score variance attributable to different sources (18). A reliability coefficient of 0.85 signifies that 85% of the variance in test scores depends on true variance in the trait measured and 15% depends on error variance.

### Specific Reliability and Agreement Statistics

There are several statistical measures for estimating interrater agreement and reliability. Four statistics commonly used to determine agreement are the frequency ratio, point-by-point agreement ratio, kappa ( $\kappa$ ) coefficients, and Lawlis and Lu's  $\chi^2$  and  $T$ -index statistics. For reliability calculations, the most frequently used correlation statistics are the Pearson product-moment (Pearson  $r$ ) and intraclass correlation coefficients (ICCs). When determining reliability for dichotomous or ordinal data, specific ICC formulas have been developed. These nonparametric ICC statistics have been shown to be the equivalent of the weighted kappa ( $\kappa_w$ ) (56–59). Consequently, the  $\kappa_w$  also can be used as an index of reliability for discrete data, and the values obtained can be directly compared with equivalent forms of ICCs (57). The method of choice for reliability and agreement analyses partially depends on the assessment strategy used (45,48,51,60). In addition to agreement and reliability statistics, standard errors of measurement (SEM) provide a clinically relevant index of reliability expressed in test score units. Each statistic is described below.

#### Frequency Ratio

This agreement statistic is indicated for frequency count data (47). A frequency ratio of the two examiners' scores is calculated by dividing the smaller total by the larger total and multiplying by 100. This statistic is appealing because of its computational and interpretive simplicity. There are a variety of limitations, however. It only reflects agreement of the total number of behaviors scored by each observer; there is no way to determine whether there is agreement for individual responses using a frequency ratio. The value of this statistic may be inflated if the observed behavior occurs at high rates (60). There is no meaningful lower bound of acceptability (49).

#### Point-by-Point Agreement Ratio

This statistic is used to determine if there is agreement on each occurrence of the observed behavior. It is appropriate when there are discrete opportunities for the behavior to occur or for distinct response categories (47,61,62). To calculate this ratio, the number of agreements is totaled by determining the concurrence between observers regarding the

presence or absence of observable responses during a given trial, recording interval, or for a particular behavior category. Disagreements are defined as instances in which one observer records a response and the other observer does not. The point-by-point agreement percentage is calculated by dividing the number of agreements by the number of agreements plus disagreements and multiplying by 100 (62). Agreement generally is considered to be acceptable at a level of 0.80 or above (62).

The extent to which observers are found to agree is partially a function of the frequency of occurrence of the target behavior and of whether occurrence and/or nonoccurrence agreements are counted (61). When the rate of the target behavior is either very high or very low, high levels of interobserver agreement are likely for occurrences or nonoccurrences, respectively. Consequently, if the frequency of either occurrences or nonoccurrences is high, a certain level of agreement is expected simply owing to chance. In such cases, it is often recommended that agreements be included in the calculation only if at least one observer recorded the occurrence of the target behavior. In this case, intervals during which none of the observers records a response are excluded from the analysis. It is important to identify clearly what constitutes an agreement when reporting point-by-point percentage agreement ratios because the level of reliability is affected by this definition.

### **Kappa Coefficients**

The  $\kappa$  coefficient provides an estimate of agreement between observers, corrected for chance agreement. This statistic is preferred for discrete categorical (nominal and ordinal) data because, unlike the two statistics discussed above, it corrects for chance agreements. In addition, percentage agreement ratios often are inflated when there is an unequal distribution of scores between rating categories. This often is the case in rehabilitation medicine, in which the frequency of normal characteristics is much higher than abnormal characteristics (63,64). By contrast,  $\kappa$  coefficients provide accurate estimates of agreement, even when scores are unequally distributed between rating categories (64).

Kappa coefficients are used to summarize observer agreement and accuracy, determine rater consistency, and evaluate scaled consistency among raters (60). Three conditions must be met to use  $\kappa$ :

1. The patients or research subjects must be independent.
2. The raters must independently score the patients or research subjects.
3. The rating categories must be mutually exclusive and exhaustive (63,64).

The general form of  $\kappa$  is a coefficient of agreement for nominal scales in which all disagreements are treated equally (45,48,51,65–68). The  $\kappa_w$  statistic was developed for ordinal data (48,51,69,70), in which some disagreements have greater gravity than others (e.g., the manual muscle testing scale, in which the difference between a score of 2 and 5 is of more

concern than the difference between a score of 4 and 5). Refer to the references cited above for formulas used to calculate  $\kappa$  and  $\kappa_w$ .

Several other variations of  $\kappa$  have been developed for specific applications. The kappa statistic  $\kappa_v$  provides an overall measure of agreement, as well as separate indices for each subject and rating category (71). This form of  $\kappa$  can be applied in situations in which subjects are not all rated by the same set of examiners. The variation of  $\kappa$  described by Fleiss et al. is useful when there are more than two ratings per patient (58); a computer program is available to calculate this statistic (63). When multiple examiners rate patients and a measure of overall conjoint agreement is desired, the kappa statistic  $\kappa_m$  is indicated (72). Standard  $\kappa$  statistics treat all raters or units symmetrically (58). When one or more of the ratings are considered to be a standard (e.g., scores from an experienced rater), alternate analysis procedures should be used (72–74).

### **Lawlis and Lu $\chi^2$ and $T$ Index**

These measures of agreement are recommended for continuous data (45). They permit the option of defining seriousness of disagreements among raters. A statistically significant  $\chi^2$  indicates that the observed agreement is greater than that expected owing to chance. The  $T$  index is used to determine whether agreement is low, moderate, or high. The reader is referred to Tinsley and Weiss (45) for a discussion of the indications for, calculation of, and interpretation of these statistics.

### **Pearson Product-Moment Correlation Coefficient**

Historically, the Pearson  $r$  has been used commonly as an index of reliability. It has limited application, however, because it is a parametric statistic intended for use with continuous bivariate data. The generally accepted minimum level of this coefficient is 0.80; however, levels above 0.90 often are considered more desirable (35,52). The Pearson  $r$  provides only an index of the strength of the relationship between scores and is insensitive to consistent differences between scores. Consequently, a linear regression equation must be reported in addition to the Pearson  $r$  to indicate the nature of the relationship between the scores (18). Because the Pearson  $r$  is limited to the analysis of bivariate data, it is preferable to use an ICC to assess reliability because ICC can be used for either bivariate or multivariate data. The Pearson  $r$  and ICC will yield the same result for bivariate data (75).

### **Intraclass Correlation Coefficients**

ICCs provide an index of variability resulting from comparing rating score error with other sources of true score variability (43,53,76). As indicated above, it is the coefficient of choice for reliability analyses. The ICC is based on the variance components from an analysis of variance (ANOVA), which includes not only the between-subject variance, as does the Pearson  $r$ , but also other situation-specific variance components, such as alternate test forms, maturation of subjects between ratings, and other sources of true mean differences

in the obtained ratings (77). The individual sources of error can be analyzed to determine their percentage contribution to the overall error variance using generalizability analysis (54,55). For further information regarding the use of generalizability theory to distinguish between sources of error, the reader is referred to Brennan (78) and Cronbach et al. (79).

There are six different ICC formulas (55). The correct ICC formula is selected based on three factors:

1. The use of a one-way versus two-way ANOVA
2. The importance of differences between examiners' mean ratings
3. The analysis of an individual rating versus the mean of several ratings (45,55)

Selection of the proper formula is critical and is based on the reliability study design (55,77,80). It is important to report which type of ICC is used to compute reliability because the calculations are not equivalent. Variations of the ICC formulas also exist for calculating ICCs using dichotomous (81) and ordinal (44) nonparametric data. The marginal distributions do not have to be equal, as was originally proposed for nonparametric ICCs (57). These nonparametric ICC formulas have been demonstrated to be equivalent to weighted  $\kappa$  coefficients, provided that the mean difference between raters is included as a component of variability and the rating categories can be ordered (57).

### ***Standard Error of Measurement***

It has been suggested that measurement error estimates are the most desirable index of reliability (18,35,76). The SEM is an estimate, in test score units, of the random variation of a person's performance across repeated measures. The SEM is an expression of the margin of error between a person's observed score and his or her true ability (47). The SEM is an important indicator of the sensitivity of the test to detect changes in a person's performance over time.

The formula for the SEM is

$$SD\sqrt{1-r_{rr}}$$

where SD is the standard deviation of the test scores and  $r_{rr}$  is the reliability coefficient for the test scores (35,46,76). Correlating scores from two forms of a test is one of several ways to estimate the reliability coefficient (76) and often is used in psychology when parallel forms of a test are available. In rehabilitation medicine, however, equivalent forms of a test often are not available. The test-retest reliability coefficient, therefore, is the coefficient of choice for calculating the SEM in most rehabilitation applications because the primary interest is in the variation of subject performance. The SEM is a relatively conservative statistic, requiring larger data samples (approximately 300 to 400 observations) in order to not overestimate the error (15).

It is best to report a test score as a range rather than as an absolute score. The SEM is used to calculate the range of

scores (i.e., confidence interval) for a given person; that is, the person's true performance ability is expected to fall within the range of scores defined by the confidence interval. A person's score must fall outside of this range to indicate with confidence that a true change in performance has occurred. Based on a normal distribution, a 95% confidence interval would be approximately equal to the mean  $\pm 2$  SEM. A 95% confidence interval is considered best to use when looking for change over time. This rigorous level of confidence minimizes the likelihood of a type I error (i.e., there is only a 5% chance that differences between scores obtained from a given person during different test sessions will not fall within the 95% confidence interval upper and lower values). Consequently, there is less than a 5% chance that differences between scores exceeding the upper end of the confidence interval are due to measurement error (i.e., they have a 95% chance of representing a true change in performance).

### **Factors Affecting Reliability**

There are four sources of measurement error for interrater reliability (18,46):

1. Lack of agreement among scorers
2. Lack of consistent performance by the individual tested
3. Failure of the instrument to measure consistently
4. Failure of the examiner to follow the standardized procedures to administer the test

Threats to test-retest reliability similarly are caused by four factors:

1. The instrument
2. The examiner
3. The patient
4. The testing protocol

Sources and prevention of examiner error will be discussed in the section on "Principles of Evaluation, Testing, and Interpretation."

There are several factors conducive to good reliability of a measure (46). These factors are the power to discriminate among ability groups; sufficient time allotted so that each patient can show his or her best performance without being penalized for an unrepresentative poor trial; test organization to optimize examinee performance; and test administration and scoring instructions that are clear and precise. Additionally, the testing environment should support good performance, and the examiner must be competent in administering the test. For tests designed to be appropriate for a wide age range, reliability should be examined for each age level rather than for the group as a whole (54).

In summary, reliability and agreement are essential components to any objective measurement. Measurements lacking test-retest reliability contain sufficient error as to be useless because the data obtained do not reflect the variable measured (18). Reliability is an important component of validity, but good reliability or agreement does not guarantee that a measure is valid. A reliable measurement is consistent, but not

necessarily correct. However, a measurement that is unreliable cannot be valid.

### **Validity**

Validity is defined as the accuracy with which a test measures that which it is intended to measure. Application of the concept of validity refers to the appropriateness, meaningfulness, and usefulness of a test for a particular situation (18). Validity is initially investigated while a test or instrument is being developed and confirmed through subsequent use. Four basic aspects of validity will be discussed: content, construct, criterion-related, and face validity.

#### **Content Validity**

Content validity is the systematic examination of the test content to determine if it covers a representative sample of the behavior domain to be measured. It should be reported in the test manual as descriptive information on the skills covered by the test, number of items in each category, and rationale for item selection. Content validity generally is evidenced by the opinion of experts that the domain sampled is adequate. There are two primary methods that the developer of a test can use for obtaining professional opinions about the content validity of an instrument (82). The first is to provide a panel of experts with the items from the test and request a determination of what the battery of items is measuring. The second method requires providing not only the test items but also a list of test objectives so that experts can determine the relationship between the two. For statistical analysis of content validity, the reader is referred to Thorn and Deitz (83).

#### **Construct Validity**

Construct validity refers to the extent to which a test measures the theoretical construct underlying the test. Construct validity should be obtained whenever a test purports to measure an abstract trait or theoretical characteristics about the nature of human behavior such as intelligence, self-concept, anxiety, school or work readiness, or perceptual organization. The following five areas must be considered with regard to construct validity in test instruments (35,82).

#### **Age Differentiation**

Any developmental changes in children or changes in performance due to aging must be addressed as part of the test development.

#### **Factor Analysis**

Factor analysis is a statistical procedure that can be performed on data obtained from testing. The purpose of factor analysis is to simplify the description of behavior by reducing an initial multiplicity of variables to a few common underlying factors or traits that may or may not be pertinent to the construct or constructs that the test was originally designed to measure. The reader is referred to Cronbach (76), Wilson et al. (84), Wright and Masters (85), and Wright and Stone

(86) for in-depth discussions of factor analysis. The more recent development of confirmatory factor analysis (87,88) overcomes the relative arbitrariness of traditional factor analysis methods. Confirmatory factor analysis differs from traditional factor analysis in that the investigator specifies, before analysis, the measures that are determined by each factor and which factors are correlated. The specified relationships are then statistically tested for goodness of fit of the proposed model compared with the actual data collected. Confirmatory factor analysis is therefore a more direct assessment of construct validity than is traditional factor analysis. Rasch modeling (89) is a further expansion on confirmatory factor analysis methods for the purpose of establishing construct validity of a measurement tool. The family of Rasch measurement models provides the means for constructing interval measures from raw data (26). Rasch models start with a carefully thought-out and systematically implemented analogy used to facilitate the construction of the concepts of the measurement tool in concrete terms and then use a developmental pathway analogy to develop the Rasch concepts of unidimensionality, fit, difficulty/ability estimation and error, locations for item difficulties, and locations for person abilities.

#### **Internal Consistency**

In assessing the attributes of a test, it is helpful to examine the relationship of subscales and individual items to the total score. This is especially important when the test instrument has many components. If a subtest or item has a very low correlation with the total score, the test developer must question the subtest's validity in relation to the total score. This technique is most useful for providing confirmation of the validity of a homogeneous test. A test that measures several constructs would not be expected to have a high degree of internal consistency. For dichotomous data, the Kuder-Richardson statistic is used to calculate internal consistency (35). Cronbach's coefficient alpha ( $\alpha$ ) is recommended when the measure has more than two levels of response (35). The minimum acceptable level generally is set at 0.70 (90).

#### **Convergent and Divergent Validity**

Construct validity is evidenced further by high correlations with other tests that purport to measure the same constructs (i.e., convergent validity) and low correlations with measures that are designed to measure different attributes (i.e., divergent validity). It is desirable to obtain moderate levels of convergent validity, indicating that the two measures are not measuring identical constructs. If the new test correlates too highly with another test, it is questionable whether the new test is necessary because either test would suffice to answer the same questions. Moderately high but significant correlations indicate good convergent validity, but with each test still having unique components. Good divergent validity is demonstrated by low and insignificant correlations between

two tests that measure theoretically unrelated parameters, such as an activity of daily living assessment and a test of expressive language ability.

### ***Discriminant Validity***

If two groups known to have different characteristics can be identified and assessed by the test, and if a significant difference between the performances of the two groups is found, then incisive evidence of discriminant validity is present.

### ***Criterion-Related Validity***

Criterion-related validity includes two subclasses of validity: concurrent validity and predictive validity (35,47). The commonality between these subclasses of validity is that they refer to multiple measurement of the same construct. In other words, the measure in question is compared with other variables or measures that are considered to be accurate measures of the characteristics or behaviors being tested. The purpose is to use the second measure as a criterion to validate the first measure.

Criterion-related validity can be assessed statistically, providing clear guidelines as to whether a measure is valid. Frequently, the paired measurements from the tests under comparison have different values. The nature of the relationship is less important than the strength of the relationship (18). Ottenbacher and Tomchek (91) showed that the limits of agreement technique provided the most accurate measurement error when comparing test results versus other statistics frequently used for such comparisons.

### ***Concurrent Validity***

Concurrent validity deals with whether an inference is justifiable at the present time. This is typically done by comparing results of one measure against some criteria (e.g., another measure or related phenomenon). If the correlation is high, the measure is said to have good concurrent validity. Concurrent validity is relevant to tests used for diagnosis of existing status, rather than predicting future outcome.

### ***Predictive Validity***

Predictive validity involves a measure's ability to predict or forecast some future criterion. Examples include performance on another measure in the future, prognostic reaction to an intervention program, or performance in some task of daily living. Predictive validity is difficult to establish and often requires collection of data over an extended period of time after the test has been developed. Hence, very few measures used in rehabilitation medicine have established predictive validity. A specific subset of predictive validity that is important to rehabilitation medicine practice is ecological validity. This concept involves the ability to identify impairments, functional limitations, and performance deficits within the context of the person's own environment. Measures with good concurrent validity sometimes are presumed to have good predictive validity, but this may not be a correct assumption.

Unless predictive validity information exists for a test, extreme caution should be exercised in interpreting test results as predictors of future behavior or function.

### ***Face Validity***

Face validity is not considered to be an essential component of the validity of a test or measure. It reflects only whether a test appears to measure what it is supposed to, based on the personal opinions of those either taking or giving the test (92). A test with high face validity has a greater likelihood of being more rigorously and carefully administered by the examiner, and the person being tested is more likely to give his or her best effort. Although it is not essential, in most instances, face validity is still an important component of test development and selection. Exceptions include personality and interest tests when the purpose of testing is concealed to prevent patient responses from being biased.

### ***Summary***

The information discussed in this section provides the basis for critically assessing available tests and measures. The scale of the test or instrument should be sufficiently sophisticated to discriminate adequately between different levels of the behavior or function being tested. The purposes for testing must be identified, and the test chosen should have been developed for this purpose. The measure selected should be practical from the standpoint of time, efficiency, budget, equipment, and the population being tested. Above all, the measure must have acceptable reliability, agreement, and validity for the specific application it is selected. Reliability, agreement, and validity are important for both clinical and research applications. The power of statistical tests depends on adequate levels of reliability, agreement, and validity of the dependent measures (93). Consequently, it is essential that adequate levels of reliability, agreement, and validity be assessed and reported for dependent measures used in research studies.

For additional information on the test development process, the reader is referred to Miller (94). For information on the principles of tests and measurements, the reader is referred to Anastasi and Urbina (35), Baumgartner and Jackson (46), Cronbach (76), Safrit (52), Rothstein (18), Rothstein and Echternach (15), and Verducci (53).

Identification of the most appropriate test for a given application, based on the psychometric criteria discussed above, does not guarantee that the desired information will be obtained. Principles of evaluation, testing, and interpretation must be followed to optimize objective data acquisition.

## **PRINCIPLES OF EVALUATION, TESTING, AND INTERPRETATION**

Systematic testing using standardized techniques is essential to quantify a patient's status objectively. Standardized testing is defined as using specified test administration and scoring

procedures, under the same environmental conditions, with consistent directions (35,47). Standardized testing is essential to permit comparison of test results for a given person over time and to compare test scores between patients (92). In addition, consistent testing techniques facilitate interdisciplinary interpretation of clinical findings among rehabilitation professionals and minimize duplication of evaluation procedures.

### Examiner Qualifications

Assessments using objective instrumentation or standardized tests must be conducted by examiners who have appropriate training and qualifications (14,16,17,35,92,95). The necessary training and expertise varies with the type of instrument or test used. The characteristics common to most rehabilitation medicine applications will be discussed. Examiners must be thoroughly familiar with standardized test administration, scoring, and interpretation procedures. Training guidelines specified in the published test manual must be strictly adhered to. A skilled examiner is aware of factors that might affect test performance and takes the necessary steps to ensure that the effects of these factors are minimized. Interrater reliability needs to be attained at acceptable levels with examiners who are experienced in administering the test to ensure consistency of test administration and scoring.

Examiners also must be knowledgeable about the instruments and standardized tests available to assess parameters of interest. They need to be familiar with relevant research literature, test reviews, and the technical merits of the appropriate tests and measures (14,16,17,35). From this information, examiners should be able to discern the advantages, disadvantages, and limitations of using a particular test or device. Based on the purpose of testing and characteristics of the person being assessed, examiners need to be able to select and justify the most appropriate assessment method from the available options.

When interpreting test results, examiners must be sensitive to factors that may have affected test performance (35). Conclusions and recommendations should be based on a synthesis of the person's scores, the expected measurement error, any factors that might have influenced test performance, the characteristics of the given person compared with those of the normative population, and the purpose of testing versus the recommended applications of the test or instrument. Written documentation of test results and interpretation should include comments on any potential influence of the above factors.

### Examiner Training

Proper training of examiners is critical to attaining an acceptable level of interrater reliability for test administration and scoring (92). Examiners should be trained to minimize later decrements in performance (60). Training methods should be documented carefully so that they can be replicated by future examiners.

### Training Procedures

As part of their training, examiners should read the test manual and instructions carefully. Operational definitions

and rating criteria need to be memorized verbatim (96). A written examination should be administered to document the examiners' assimilation of test administration and scoring procedures (60). This information should be periodically reviewed to produce close adherence to the standardized protocol. It is helpful for examiners to view a videotape of an experienced examiner conducting the test. If test administration and scoring techniques need to be adjusted for the varying abilities of the target population (e.g., children of different age levels), the experienced examiner should be observed testing a representative sample from the target population to demonstrate the various testing, scoring, and interpretation procedures.

Videotapes also are useful to clarify scoring procedures and establish consistency of scoring between and within raters (67,92). Once scoring procedures have been reviewed adequately, interrater reliability can be established by having trainees view several patients on videotape and then compare their scores with those from an experienced examiner. Scoring discrepancies should be discussed, and trainees should continue to score videotaped segments until 100% agreement is established with an experienced examiner (96). Intrarater consistency of scoring also can be established by having an individual examiner score the same videotape on multiple occasions. Sufficient time should elapse between multiple viewings so examiners do not recall previous ratings.

For assessments that involve multiple trials (e.g., strength assessments), intertrial reliability can be calculated to provide a measure of the examiner's consistency of administering multiple trials within a given test session. As was mentioned previously, intertrial reliability also is influenced by factors such as fatigue, motor learning, motivation, and the stability of performance over a short period of time. Multiple trials administered during a given session generally are highly correlated; thus, intertrial reliability coefficients are expected to be very high. Although this measure provides feedback on consistency in administering multiple trials, it should not be considered a substitute for establishing other types of reliability during the training phase.

### Establishing Procedural Reliability

Procedural reliability is defined as the reliability with which standardized testing and scoring procedures are applied. As part of training, examiners should be observed administering and scoring the test on a variety of people with characteristics similar to those of the target population (92). Procedural reliability should be established by having an experienced examiner observe trainees to determine if the test is being administered and scored according to the standardized protocol. Establishing procedural reliability greatly increases the likelihood that the observed changes in performance reflect true changes in status and not alterations in examiner testing or scoring methods. Unfortunately, this type of reliability often is neglected. According to Billingsley et al. (97), failure to assess procedural reliability poses a threat to both the internal and the external validity of assessments.

Procedural reliability is assessed by having an independent observer check off whether each component of an assessment is completed according to the standardized protocol while viewing a live or videotaped assessment. Specific antecedent conditions, commands, timing of execution, and positioning are monitored, and any deviations are noted. Procedural reliability is calculated as a percentage of correct behaviors (97). Checklists should include all essential components of the standardized protocol. An example of a procedural reliability checklist for selected items on the MAP is provided in Figure 8-1 (92). In this example, the checklist varies for each item administered. Another example of procedural reliability is referenced for strength testing using a myometer (98). In this case, the protocol was standardized across muscle groups, including the command sequence, tactile input, myometer placement, start and end positions, and contraction duration.

Deviation from the standardized protocol can be minimized by conducting periodic procedural reliability checks (97). Procedural reliability should be assessed on an ongoing basis at random intervals in clinical or research settings, in addition to the training period. Assessments should be conducted at least once per phase during a research study. Examiners should be informed that procedural reliability checks will occur randomly and ideally should be unaware of when specific assessments are conducted to avoid examiner reactivity. A minimum acceptable level of procedural reliability should be established for clinical or research use (generally, 90% to 100%). During

the training phase, a 100% level should be attained. Feedback on procedural reliability assessments should be provided to examiners. If an examiner's score decreases below the acceptable level, pertinent sections of the standardized protocol should be reviewed.

### Establishing Interrater Reliability and Agreement

Once an examiner has demonstrated consistency in scoring by viewing videotaped assessments and reliability in test administration through procedural reliability checks, then interrater reliability and agreement should be established with an experienced examiner (60,92). Both examiners should independently rate people with characteristics similar to the target population. Reliability and agreement assessments should be conducted under conditions similar to those of the actual data collection procedures (61). As with procedural reliability, interrater assessments should be conducted periodically in both clinical and research settings. It is essential to establish interrater reliability and agreement at least once per phase in a research study to determine the potential influence of examiner rating differences on the data recorded (60,61). When calculating interrater agreement when the experienced examiner's scores are considered to be a standard, specific statistical procedures are indicated (72–74).

For assessments where the person's performance can be observed directly (e.g., developmental or activities of daily living assessments), it is preferable to establish interrater reliability and agreement with the examiner in training administering the test while the experienced examiner simultaneously observes and independently scores the person, so that pure interrater reliability and agreement can be assessed. When measuring parameters such as range of motion, sensation, or strength, it is imperative that both examiners independently conduct the tests because the measurement error depends to a large extent on the examiner's skill and body mechanics in administering the test. In addition, direct observation of these parameters by each examiner is required. In these instances, interrater reliability and agreement are confounded by factors of time and variation in patient performance, as discussed above in the section on "Interrater Reliability and Agreement."

If examiners are aware that interrater reliability and agreement is being assessed, the situation is potentially reactive (61). Reactivity refers to the possibility that behavior may change if the examiners realize they are being monitored. Examiners demonstrate higher levels of reliability and agreement when they are aware that they are being observed. It is difficult, however, to conduct reliability and agreement assessments without examiner awareness; consequently, during a research study, it might be best to lead examiners to believe that all of their observations are being monitored throughout the investigation (61). It is important to note that levels of reliability and agreement attained when examiners are aware that they are being monitored are potentially inflated compared with examiner performance in a typical clinical setting where monitoring occurs infrequently.

#### TOWER: "THE BIG BUILDING GAME"

- \_\_\_\_\_ Blocks placed on table before child enters testing room.
- \_\_\_\_\_ Demonstration model left standing until child begins building.
- \_\_\_\_\_ Number stacked recorded correctly.

#### SEQUENCING: "THE PUT AWAY GAME"

- \_\_\_\_\_ Six blocks placed approximately 1 in apart and 4 in from table edge closest to child, parallel to table edge.
- \_\_\_\_\_ Container centered behind blocks.
- \_\_\_\_\_ Demonstration started on child's left side, all blocks returned to table for child to begin item.
- \_\_\_\_\_ Suggested wording used.
- \_\_\_\_\_ No clues given after child begins task.
- \_\_\_\_\_ Pass/fail recorded correctly.

#### BLOCK DESIGNS: "THE MAKE-A-BUILDING GAME"

- \_\_\_\_\_ Exact number of blocks placed in front of child.
- \_\_\_\_\_ Model #1 taken down before building #2.
- \_\_\_\_\_ Mirror image of design (from cue sheet) built for demonstration.
- \_\_\_\_\_ Designs demonstrated quickly.

#### GENERAL POINTS:

- \_\_\_\_\_ Card notebook set up for correct age group of child.
  - \_\_\_\_\_ Child's age determined correctly.
  - \_\_\_\_\_ Examiner adapts to pace of child yet keeps test administration moving along.
-

### Detecting Examiner Errors

When training examiners in the use of rating scales, interrater reliability and agreement data should be examined to determine if there are any consistent trends indicative of examiner rating errors. These data should be obtained from testing patients who represent a broad-range sample of pertinent characteristics of the population, so that a relatively normal score distribution is expected. In many circumstances, a representative group of patients can be observed efficiently on videotape by multiple examiners. The distribution of examiners' scores across patients is then compared for error trends (53). If only one examiner is using a given rating scale, so that multiple examiners' scores cannot be compared for rating errors, rating errors still can be detected by examining the distribution of one examiner's ratings across multiple patients. Rasch analysis is another useful method for detecting examiner errors on specific items or as an overall trend. Rating errors can be classified into five categories:

1. Error of central tendency
2. Error of standards
3. Halo effect error
4. Logical error
5. Examiner drift error

An indication of an error of central tendency is when one rater's scores are clustered around the center of the scale and the other rater's scores are spread more evenly over the entire scale. Errors of standards occur when one rater awards either all low or all high scores, indicating that his standards are set either too high (i.e., error of severity) or too low (i.e., error of leniency), respectively. Leniency errors are the most common type of rating error (53). Halo effect errors can be detected if several experienced examiners rate a number of people under identical conditions and the score distributions are examined. There should be little variability between well-trained examiners' scores. If one examiner's scores fall outside of this limited range of variability, a halo rating error may have occurred as a result of preset examiner impressions or expectations. A logical error occurs when multiple traits are rated and an examiner awards similar ratings to traits that are not necessarily related.

A fifth type of rating error is examiner drift. Examiner drift refers to the tendency of examiners to alter the manner in which they apply rating criteria over time (61). Examiner drift is not easily detected. Interrater agreement may remain high even though examiners are deviating from the standardized rating criteria (60,61). This occurs when examiners who work together discuss rating criteria to clarify rating definitions. They may inadvertently alter the criteria, diminishing rating accuracy, and yet high levels of interrater agreement are maintained. If examiners alter rating criteria over time, data obtained from serial examinations may not be comparable. Examiner drift can be detected by assessing interrater agreement between examiners who have not worked together or by comparing ratings from examiners who have

been conducting assessments for an extended period of time with scores obtained from a newly trained examiner (61). Presumably, recently trained examiners adhere more closely to the original criteria than examiners who have had the opportunity to drift. Comparing videotaped samples of patient performance from selected evaluation sessions with actual examiner ratings obtained over time is another method of detecting examiner drift.

### Reducing Examiner Errors

Examiner ratings can be improved in several ways (53,60,61). Operational definitions of the behavior or trait must be clearly stated, and examiners must understand the rating criteria. If examiners periodically review rating criteria, receive feedback on their adherence to the test protocol through procedural reliability checks, and are informed of the accuracy of their observations through interrater agreement checks, examiner drift can be minimized. Examiners should be aware of common rating errors and how these errors may influence their scoring. Adequate time needs to be provided to observe and rate behaviors. If the observation period is too brief for the number of behaviors or people to be observed, rating accuracy is adversely affected. The reliability of ratings also can be improved by averaging ratings from multiple observers because the effects of individual rater biases tend to be balanced. Averaging multiple scores obtained from one rater is not advantageous for reducing rating error, however, because a given rater's errors tend to be relatively constant.

The complexity of observations negatively affects interrater reliability and agreement because observers may have difficulty discriminating between rating criteria (61). With more complex observations, examiners need to attain higher levels of agreement for each behavior during the training phase. These high levels of interrater agreement need to be achieved under the exact conditions that will be used for data collection (61). If multiple behaviors are observed on several patients, it is best to rate all patients on one behavior before rating the next behavior. This practice facilitates more consistent application of operational definitions and rating criteria for the individual behavior. It also tends to reduce the incidence of logical errors.

Another method for improving scoring is to make raters aware of examiner idiosyncrasies or expectations that can affect ratings. According to Verducci (53), there are five patient-rater characteristics that may affect scoring:

1. If an examiner knows the person being evaluated, ratings can be either positively or negatively influenced. The longer the prior relationship has existed, the more likely the ratings will be influenced.
2. The rater tends to rate more leniently if the rater is required to disclose ratings directly to the person or if the person confronts the examiner about the ratings.
3. Examiner gender also can influence ratings. In general, male examiners tend to rate more leniently than female examiners.

4. There is a tendency to rate members of one's sex higher than those of the opposite sex.
5. Knowledge of previous ratings may bias examiners to rate similarly. Consequently, examiners should remain blind to previous scores until current ratings have been assigned.

Other potential sources of rater bias are the examiner's expectations about the patient's outcome and feedback received regarding ratings (60,61). If examiners expect improvement, their ratings are more likely to show improvement. This is especially true when examiners are reinforced for patient improvement. In a research setting, examiner bias can be minimized if the observers remain blind to the purposes and hypotheses of the study. In a clinical setting, the baseline, intervention, and follow-up sessions often can be videotaped. Blind, independent observers can then rate the behaviors when shown the videotaped sessions in a random order.

### Test Administration Strategies

Consistency in test administration is essential to permit comparison of test results from one session to another or between people. Multiple factors that might influence performance must be held constant during testing. These factors include test materials and instrumentation, the testing environment, test procedures and scoring, state of the person being assessed, observers present in the room, and time of day. Examiners must be aware of the potential influence of these factors and document any conditions that might affect test performance. Examiners ideally should remain blind to previous test results until after conducting the evaluation to avoid potential bias.

If more than one method is acceptable for testing, it is important to document which protocol is used so that the same method can be used during future evaluations. If it is necessary to alter the method of measurement as a result of a change in status or the development of an improved measurement technique, measurements should be taken using both the new and old methods so there is overlap of at least one evaluation. This overlap permits comparison with previous and future test results so that trends over time can be monitored.

Multiple trials should be administered when assessing traits, such as muscle strength, which require consistent efforts on the part of the patient. An average score of multiple trials is more stable over time than a single effort (98). A measure of central tendency and the range of scores both should be reported.

Standardized test positions always should be used unless a medical condition prevents proper positioning (e.g., joint contractures). In this event, the patient should be positioned as closely as possible to the standardized position, and the altered position should be documented. It is important to make sure that patients are posturally secure and comfortable during the evaluation. For patients with neurologic involvement, the head should be positioned in neutral to avoid subtle influences of tonic neck reflexes. An exception occurs when testing is conducted in the prone position.

In this case, the head should be turned consistently toward the side being tested.

A key to obtaining reliable and valid test results is providing clear directions and demonstrations to the patient. Standardized instructions always must be provided verbatim and may not be modified or repeated unless specifically permitted in the test manual. Verbal directions often are enhanced by tactile, kinesthetic, and visual cues, if permitted. If confusion about the task is detected, this should be documented. If the examiner believes that a given patient could complete a task successfully with further instructions that are not specified in the standardized protocol, this item can be readministered at the end of the test session. The person's test score should be based solely on performance exhibited when given standardized instructions. Test performance with augmented instructions can be documented in the clinical note but should not be considered when scoring.

When conducting tests that do not have standardized instructions (e.g., strength testing), it is important to use short, simple, and consistent commands. If repetitive or sustained efforts are required, the examiner's voice volume needs to be consistent and adequate to heighten the arousal state and motivate patients to give their best effort.

Verbal reinforcement and feedback regarding performance can influence performance levels (99). Consequently, it must be provided consistently, according to the procedures specified in the test manual. For tests in which reinforcement and feedback intervals are not specified and are permitted as needed, the frequency and type of feedback provided should be documented.

### Test Scoring, Reporting, and Interpretation of Scores

Examiners should be thoroughly familiar with scoring criteria so that scores can be assigned accurately and efficiently during evaluation sessions. It is not appropriate for examiners to look up scoring criteria during or after the evaluation. Uncertainty about the criteria prolongs the evaluation and leads to scoring errors. It is helpful to include abbreviated scoring criteria on the test form to assist the examiner during the evaluation. Test forms should be well organized and clearly written to facilitate efficient and accurate recording of test results. If multiple types of equipment and test positions are required, it is useful if the equipment and position are identified on the score sheet using situation codes for each item. Such a coding system expedites test administration by assisting the examiner in grouping test items with similar positioning and equipment requirements. Examples of well-organized test forms that use situation codes are the Bayley Scales of Infant Development (100), the MAP (34), and the revised version of the Peabody Developmental Motor Scales test forms (41).

If the scoring criteria for a test are not well-defined, it may be necessary for examiners within a given center or referral region to clarify the criteria. This was the case for many items on the Peabody Developmental Motor Scales. Interrater

reliability levels of highly trained examiners were low for several items, so therapists at the Child Development and Mental Retardation Center in Seattle, Washington, clarified the scoring criteria to improve reliability. Examiners in the surrounding referral area were educated about the clarified criteria by means of in-services and videotapes to ensure that all examining centers in the area would be using identical criteria (41). If scoring criteria are augmented to improve reliability, it is imperative to document that the test was administered with altered criteria. Future results are comparable only if administered using identical scoring criteria. Additionally, if scores are compared with normative data, it is important to document that the test scores obtained may not be directly comparable because altered scoring criteria were used.

Raw scores obtained from testing are meaningless in the absence of additional interpretive data. To meaningfully compare a person's current test results to previous scores, the SEM of the test must be known. To determine how a person's performance compares with that of other people, normative data must come from a representative standardized sample of people with similar characteristics. In the latter case, the raw score must be converted into a derived or relative score to

permit direct comparison with the normative group's performance. These concepts are discussed in detail below.

Raw scores may be compared with previous scores obtained from a given person to monitor changes in status. However, the SEM of the test must be known to determine if a change in a score is clinically significant. A change in a test score exceeding the SEM is indicative of a meaningful change in test performance. As was discussed earlier, in the section on "Reliability and Agreement," it is best to report test scores as a range, based on confidence intervals, rather than as an absolute score. This is because a person's score is expected to vary as a result of random fluctuations in performance. It is only when a score changes beyond the range of random fluctuation that we can be confident that a true change in performance has occurred. This true score range usually is based on the 95% confidence interval. This rigorous level of confidence minimizes the likelihood of a type I error (i.e., believing a change occurred when actually there was no change) and is considered the confidence level of choice when looking for improvement in performance, resulting from a specific treatment regimen or improved physical status. A lower level of confidence (e.g., 75%, 50%) may be desirable when monitoring the status of

**TABLE 8.2** Descriptive and Standard Scores Commonly Reported in Rehabilitation Medicine

Summary Statistic	Definition and Interpretation
Descriptive score	
Raw scores	Expressed as number of correct items, time to complete a task, number of errors, or some other objective measure of performance.
Percentage scores	Raw scores expressed as percent correct.
Percentile scores	Expressed in terms of the percentage of people in the normative group who scored lower than the client's score (e.g., a client scoring in the 75th percentile on a norm-referenced test has performed better than 75% of the people in the normative group). Often stratified for age, gender, or other pertinent modifying varieties.
Age-equivalent score	Average score for a given age group.
Grade-equivalent score	Average score for a given grade level.
Developmental age	The basal age score, plus credit for all items earned at higher age levels (up to the ceiling level of the test). Also called motor age for tests of motor development. The basal age level is defined as the highest age at and below which all test items are passed.
Scaled score	The client's total score, summed across all sections of the test. Used for comparison to previous and future scores.
Standard scores	
z score	The client's raw score minus the mean score of normative group, divided by the standard deviation of the normative group. The mean of a z score is 0 with a standard deviation of 1. Scores may be plus or minus. Reported to two significant digits.
T score	z score times 10 plus 50. The mean of a T score is 50 with a standard deviation of 10.
Stanine	Standard scores which range from 1 to 9. A stanine of 5 indicates average performance and the standard deviation is 2. Often used to minimize the likelihood of overinterpreting small differences between individual scores.
DMQ	The ratio of the client's actual score on the test (expressed as developmental age) and the client's chronologic age, $DMQ = DA/CA$ . The DMQ equals the z score times 15, plus 100. The mean DMQ is 100, with a standard deviation of 15.
Deviation IQ	A standard score deviation of the ratio between the client's actual score on the test, expressed as a mental age and the client's chronological age. The mean deviation IQ is 100, with a standard deviation of 15, based on the Wechsler deviation IQ distribution.

CA, chronological age; DA, developmental age; DMQ, developmental motor quotient; IQ, intelligence quotient; MA, motor age.

**FIGURE 8-2.** Relationships among standard scores, percentile ranks, and the normal distribution. (Adapted with permission from Anastasi A. *Psychological Testing*. 6th ed. New York: Macmillan; 1988:97.)

people who are at risk for loss of function over time. For these people, it is important to minimize the likelihood of a type II error (i.e., believing no change occurred when actually there was a change). In such cases, if a person's score falls outside a true score range that is based on a lower level of confidence, it may indicate the need to conduct further diagnostic tests or to monitor the person more closely over time.

If normative data are available for a given test, a person's score can be compared directly to the normative group's performance by converting the score into a derived or relative score. Normative scores provide relative rather than absolute information (101). Normative data should not be considered as performance standards but rather as a reflection of how the normative group performed. Derived scores are expressed either as a developmental level or as a relative position within a specified group. Derived scores are calculated by transforming the raw score to another unit of measurement that enables comparison with normative values. Most norm-referenced tests provide conversion tables of derived scores that have been calculated for the raw scores so that hand calculations are not required. However, it is important for examiners to understand the derivation, interrelationship, and interpretation of derived scores. Specific calculation of these scores is beyond the scope of this chapter. For computational details and the practical application of these statistical techniques, the reader is referred to textbooks on psychological or educational statistics and measurement theory (92,94,101).

Selection of the particular type of score to report depends on the purpose of testing, the sophistication of the people reading the reports, and the types of interpretations to be made from the results (101). Table 8-2 summarizes various descriptive and standard scores that are commonly used. Figure 8-2 shows the relationship of these scores to the normal distribution and the interrelationship of these scores. Calculation of standard scores (e.g., *z* scores, *T* scores, stanines, developmental motor quotients, deviation IQ) is appropriate only with interval or ratio data. They express where a person's performance is with regard to the mean of the normative group, in terms of the variability of the distribution. These standard scores are advantageous because they have uniform meaning from test to test. Consequently, a person's performance can be compared between different tests.

### Written Evaluation

Thorough documentation of testing procedures and results is essential in both clinical and research settings to permit comparison of test results between and within individuals. The tests administered should be identified clearly. Any deviations from the standardized procedures, such as altered test positions or modified instructions, should be documented (14). If multiple procedural options are available for a given test item (e.g., measuring for a flexion contracture at the hip), the specific method used should be specified in the report. The patient's behavior, level of cooperation, alertness, attention, and

motivation during the evaluation should be documented. Any potential effect of these factors on test performance should be stated. Other factors that might have influenced the validity of test results also should be noted (e.g., environmental factors, illness, length of test session, activity level before the test session). It should be indicated whether optimal performance was elicited. If a person's performance is compared with normative data, the degree of similarity of the person's characteristics to those of the normative group should be stated. It is imperative to distinguish between facts and inferences in the written report.

The use of a standard written evaluation format facilitates communication between and within disciplines. In addition, computerized databases provide standardized formats useful for both clinical and research purposes. Serial examinations of a given person can be reviewed easily, and a patient's status can be compared directly with that of other people with similar characteristics. Clinical and research applications of computer databases for documentation in rehabilitation medicine are discussed by Shurtleff (102) and Lehmann et al. (103).

## CONTEMPORARY MEASUREMENT TECHNIQUES

There are several potential deficiencies in current measurement methods that can negatively impact the usefulness of medical rehabilitation tests and measures across the continuum of care and research. Jette and Haley (104) include "(a) narrowly defined scope of outcome measures; (b) the inability of different outcome instruments to talk to each other; (c) the classic trade-off between feasibility of existing outcome measures versus their limitations in detecting clinically relevant changes." Two contemporary measurement techniques used for many years in educational testing, item response theory (IRT) and computer adaptive testing (CAT), can overcome these limitations.

### IRT Techniques

Jette and Haley (104) state "IRT methods examine the associations between individuals' response to a series of items designed to measure a specific outcome domain (e.g., physical functioning). Data collected from samples of rehabilitation patients are fit statistically to an underlying IRT model that best explains the covariance among item responses. IRT measurement models are a class of statistical procedures used to develop measurement scales. The measurement scales are comprised of items with a known relationship between item responses and positions on an underlying functional domain, called an item characteristic curve." The form of the relationships is typically nonlinear. Using this approach, probabilities of patients scoring a particular response on an item at various functional abilities can be modeled. Persons with more functional ability have higher probabilities of responding positively to functional items than persons with lower functional abilities. These probability estimates are used to determine the individual's most

likely position along the functional dimension. When assumptions of a particular IRT model are met, estimates of a person's functional ability do not strictly depend on a particular fixed set of items. This scaling feature allows one to compare persons along a functional outcome dimension even if they have not completed the identical set of functional outcomes. "Within rehabilitation, researchers have linked functional outcome items from an item pool to create a practical yet comprehensive set of short forms that can be applied in different rehabilitation settings. IRT methods open the door to understanding the linkages among items used to assess a common functional outcome domain, and in this way serve as the psychometric foundation for CAT."

### CAT Techniques

Jette and Haley (104) describe CAT programs as "a simple form of artificial intelligence that selects questions tailored to the test-taker, and thereby shortens or lengthens the test to achieve the level of precision desired by the user. Functional outcome CAT applications rely on extensive item pools constructed for each outcome area. They contain items that consistently scale along each functional outcome dimension from low to high proficiency, and include rules guiding starting, stopping and scoring procedures. CAT methodology uses a computer interface for the patient/clinician report that is tailored to the patient's unique ability level. The basic notion of CAT test is to mimic what an experienced clinician does. A clinician learns most when he or she directs questions at the patient's approximate proficiency level. Administering outcomes items that represent tasks that are too easy or too hard for the patient provides little information." "A CAT is programmed to first present an item from the midrange of an IRT-defined item pool, and then direct subsequent functional items to the level based on the patient's (or clinician's) previous responses, without asking unnecessary questions. The selection of an item in the mid-range is arbitrary and the CAT can be set to select an initial item based on other information entered about the patient such as age, diagnosis, or severity of condition."

## OBJECTIVE MEASUREMENT WHEN A STANDARDIZED TEST IS NOT AVAILABLE

### Rationale for Systematically Observing and Recording Behavior

Standardized tests and objective instrumentation are not always available to measure the parameters of clinical and research interests. Consequently, rehabilitation professionals often resort to documentation of subjective impressions (e.g., "head control is improved," "wheelchair transfers are more independent and efficient"). However, functional status and behaviors can be documented objectively by observing behavior using standardized techniques that have been demonstrated to be reliable. Systematically observing and

recording behavior provides objective documentation of behavior frequency and duration, identifies the timing and conditions for occurrence of a particular behavior, and identifies small changes in behavior. Several of the procedures for objective documentation described below are based on the principles of single-case research designs. These research designs have been suggested to be the most appropriate method of documentation of treatment-induced clinical change in rehabilitation populations, owing to the wide variability in clinical presentation, even within a given diagnostic category (95,105,106). In addition, such designs have been recommended to evaluate and compare the effects of two different treatments on individual patients (104). Selected single-case research concepts that specifically pertain to objective documentation for either clinical or research purposes are presented in this chapter. The reader is referred to Hayes et al. (107), Barlow and Hersen (60), Bloom et al. (47), Kazdin (61), and Ottenbacher (95) for more thorough discussions of documentation using single-case research standardized testing techniques.

## Procedures for Objective Observation and Recording of Behavior

### Step 1: Identify the Target Behavior to be Monitored

The target behavior must be identified by specifying the parameters of interest and their associated conditions. The prerequisite conditions required must be defined, such as verbal directions, visual or verbal cues, or physical assistance provided. In addition, environmental conditions must be described because different responses may be observed in the therapy, inpatient ward, or home setting. The duration, frequency, and timing of the observation period also must be specified. Ideally, these conditions should be constant from one observation period to the next for comparison purposes.

### Step 2: Operationally Define the Target Behavior

An operational definition is stated in terms of the observable characteristics of the behavior that is being monitored. The definition must describe an observable or measurable action, activity, or movement that reflects the behavior of interest. The beginning and ending of the behavior must be clearly identified. Objective, distinct, and clearly stated terminology should be used (60,95). The definition should be elaborated to point out how the response differs from other responses. Examples of borderline or difficult responses, along with a rationale for inclusion and exclusion, should be provided. An example of an operational definition used to determine success or failure in drawing a circle is provided in Figure 8-3.

### Step 3: Identify the Measurement Strategy

There are five methods of sampling behavior: event recording, rate recording, time sampling, duration recording, and discrete categorization (47,60,95). Each of these methods will be described below, along with indications and contraindications for their use.

**FIGURE 8-3.** The operational definition of a circle (*dashed lines*: circle path template; *solid line*: patient's drawing of a circle). The patient is instructed to draw a circle inside the two *dashed lines*. An adequate circle is one in which the two ends meet, and the line of the circle stays within the circle path template. It can touch the edges of the template but cannot extend beyond the edges.

### Event Recording

The number of occurrences of the behavior is tallied in a given period of time or per given velocity in the case of mobility activities. Indications for event recording include when the target response is discrete, with a definite beginning and end, or when the target response duration is constant. The target behavior frequency should be low to moderate, and the behavior duration should be short to moderate. It is best to augment the number of occurrences with real-time information to permit sequential, temporal, and reliability and agreement analyses. Contraindications for using event-recording techniques include behaviors that have a high incidence of occurrence because of the increased probability of error in counting the high-frequency behavior and behaviors that have an extended duration or that occur infrequently (60,95) (e.g., wheelchair transfers). Duration recording should be used in the latter case. The following is an example of event recording:

A man with hemiplegia successfully fastened 5 of 10 shirt buttons during a 10-minute period of time using his involved hand to hold his shirt and his uninvolved hand to manipulate the buttons. The number of successes, number of trials, and duration of the observation period were recorded.

### Rate Recording

The number of occurrences of the behavior is divided by the duration of the observation period (e.g., the number of occurrences per minute). This method is indicated when the observation period varies from session to session. Rate recording is advantageous because it reflects changes in either the duration or the frequency of response and is sensitive for detecting changes or trends because there is no theoretical upper limit. The following is an example of rate recording.

A child with Down syndrome exhibits five occurrences of undesirable tongue thrusting during a 10-minute observation period the first day and eight times during a 20-minute observation period the second day. The observations were made from videotapes recorded immediately after the child's oral motor therapy program. An independent observer, who was blind to the child's intervention program, performed the frequency counts. The rate of responding was 0.5 behaviors per minute (5 per 10 minutes) for the first day and 0.4 behaviors per minute (8 per 20 minutes) for the second day.

### ***Time Sampling***

This method involves recording the state of a behavior at specific moments or intervals in time. It also has been described in the literature as scan sampling, instantaneous time sampling, discontinuous probe time sampling, and interval sampling. Time sampling is analogous to taking a snapshot and then examining it to see if a particular behavior is occurring. This method often is used in industrial settings to determine exposure to risk factors or compliance with injury prevention techniques.

To monitor behavior using this method, the behavior of interest is observed for a short block of time (e.g., a 5-second observation period) at specified recording intervals (e.g., 5-minute intervals) during a particular activity (e.g., a 30-minute meal period). The recording interval is signaled to the observer by means of a timer, audiotape cue, or a tone generator. The target behavior is scored as either occurring or not occurring during the observation period of each recording period. Fixed (i.e., preset) or random intervals can be used, but it is important to avoid a situation in which the signal coincides with any regular cycle of behavior. The sampling should occur at various times throughout the day and in different settings to obtain a representative picture of the behavior frequency. The recording interval length depends on the behavior duration and frequency, as well as on the observer's ability to record and attend to the person. The more frequent the behavior, the shorter the interval. For low to medium response rates, 10-second intervals are recommended. For high response rates, shorter intervals should be used (108). An advantage of this type of recording is that several patients can be observed simultaneously by one rater in a group setting (e.g., during meal times or recreational events) by staggering the recording intervals for each patient.

Variations of time sampling include observing the behavior during a single block of time that is divided into short intervals (i.e., interval recording) or during brief intervals that are spread out over an entire day (i.e., time sampling); combining time sampling and event recording, when the number of responses occurring during a given interval are recorded; and combining time sampling and duration recording, when the duration of the response during a given interval is recorded. The following are examples of time sampling:

To document a patient's ability to maintain his head in an upright position, the nursing staff observed him for 15 seconds

at 5-minute intervals during one 30-minute meal period, during one 30-minute self-care/dressing period, and during one 30-minute recreation period.

To estimate compliance of 12 industrial workers with suggestions provided in a back school program, the time individual workers spent in appropriate versus inappropriate postures was recorded for 5 minutes each hour during an 8-hour shift.

### ***Duration Recording***

Either the duration of the response or the length of the latency period is recorded. The duration is reported as the total time if the observation period is constant or as the percentage of time that a behavior occurred during observation periods of varying length. Indications for this method include continuous target responses, behaviors with high or even response rates, and behaviors with varying durations, such as a wheelchair transfer, for which a frequency count would be less meaningful. The behavior duration is timed with a stopwatch, electro-mechanical event recorder, or electronic keyboard. Variations of duration recording include timing the response latency (i.e., the time that elapses between a cue and a response), measuring the time required to complete a particular task, or monitoring the time spent performing a particular activity. The following are examples of duration recording:

- The amount of time that it takes an adult with a spinal cord injury to dress in the morning
- The length of time that a child is able to stand independently with and without orthotics before losing his or her balance.

### ***Discrete Categorization***

With this method of behavior measurement, several different behaviors of interest are listed and checked off as being performed or not performed. This method is useful in determining whether certain behaviors have occurred. It is indicated when behavioral responses can be classified into discrete categories (e.g., correct/incorrect, performed/not performed). An example of this method is a checklist of the different steps for performing a wheelchair transfer, such as positioning the wheelchair, locking the brakes, removing feet from footrests, and so forth. The observer checks off whether each of these steps was performed during a given transfer.

### ***Step 4: Establish Interrater Reliability***

There are four reasons for assessing interrater (i.e., inter-observer) reliability and agreement.

1. To establish how consistently two observers can measure a given behavior
2. To minimize individual observer bias by establishing interrater reliability and then retraining observers if the level of reliability is unacceptable
3. To reduce the chances of an examiner altering or "drifting" from the standard method of rating by implementing periodic interrater reliability or agreement checks to ensure that observers are consistent over time

4. To examine the adequacy of operational definitions, rating criteria, and scoring procedures. Items that have poor agreement should be revised

Before the onset of data collection, two people should independently observe and score pilot subjects who have characteristics that are similar to those of the clinical or study population. Behaviors of interest are rated according to predetermined operational definitions. Interrater reliability and agreement are then calculated using an appropriate statistic (see section on Reliability and Agreement). The minimum acceptable level of agreement depends on the type of statistic calculated (see Table 8-1).

If interrater reliability or agreement is below the target level, improvement may occur by discussing operational definitions of the behaviors. If problems with reliability or agreement continue, it may be necessary to redefine behaviors, improve observation and recording conditions, reduce the number of behaviors being recorded, provide additional training, and, if necessary, further standardize the data collection environment (65,85). Interrater reliability or agreement should be reestablished once remedial steps have been taken. As stated previously, periodic checks of interrater reliability or agreement should be conducted in the clinic and at least once during each phase of a research study (64,65). Reliability and agreement data should be plotted along with clinical or research data to show the level of consistency in measurements.

### Step 5: Report Scores and Graph Data

Baseline, intervention, and follow-up data should be plotted on a graph or chart to provide a pictorial presentation of the results. Graphing strategies include using standard graph paper or a standard behavior chart (i.e., six-cycle graph paper). Advantages of the latter are that it permits systematic, standardized recording using a semilog scale that allows estimation of linear trends. Extremely high and low rates can be recorded on the chart. Behavior rates that range from once per 24 hours to 1,000 per minute can be accommodated; therefore, data are not lost as a result of floor or ceiling effects. In addition, continuous recording of data for up to 20 weeks is permitted. For further information on graphing strategies, the reader is referred to White and Haring (109) and Carr and Williams (110) for use of the standard behavior chart in clinical settings.

The time period of data collection is plotted on the horizontal axis (e.g., hours, days, weeks) and changes in the target behavior on the vertical axis. Appropriate scaling should be used to accommodate the highest expected response frequency and the longest anticipated documentation period duration. The measurement interval on both axes should be large enough to permit visual detection of any changes in behavior. Interrater reliability data from each phase should be plotted on the same graph, along with the study results, as discussed previously.

### Considerations When Reporting Scores

The percentage of correct scores often is reported because of the ease of calculation and interpretation. However, usefulness of this summary statistic is limited because it does not provide

information on the number of times a patient has performed correctly (95). Consequently, it can be misleading if the total number of opportunities varies from day to day. For example, three successes of six trials on day 1 versus three successes out of four trials on day 2 would yield percentages of 50% and 75%, respectively. Based on percentage scores, it would appear that the patient's performance was improved, and yet the absolute number of successes has not changed. Additionally, if an odd number of trials are administered on some days and an even number of trials on other days, performance changes may occur based on percentage scores simply because it is not possible to receive half credit for a trial on days when an odd number of trials are given (e.g., five successes out of ten trials vs. three successes out of five trials).

## SUMMARY

Rehabilitation practitioners and researchers in rehabilitation medicine increasingly are using objective tests and measurements as a scientific basis for communication, to establish credibility with other professionals, and to document treatment effectiveness. The increased use of such measures has resulted in greater responsibility of the user for appropriate implementation and interpretation of tests and measures. Rehabilitation professionals must be familiar with the principles of objective measurement to use the tools properly.

The section "Psychometric Parameters Used to Evaluate Tests and Measures" of this chapter described the psychometric parameters used to evaluate the state of development and quality of available objective measures. The four basic levels of measurement—nominal, ordinal, interval, and ratio scales—were defined. The purposes for testing were discussed, including screening tests, in-depth assessment tests, and criterion-referenced tests. Several issues of practicality for selection and use of tests also were identified. The various forms of reliability, agreement, and validity described are of great importance for using the various measurements effectively. A test that does not provide reproducible results, or does not measure what it is purported to measure, is of no value and is potentially harmful by giving a false implication of meaningfulness. Consequently, caution in the use and interpretation of test results must be exercised when information on reliability or validity of a measure is not available or if their values are below accepted levels.

The section "Principles of Evaluation, Testing, and Interpretation" of this chapter discussed the principles of evaluation, testing, and interpretation that help to ensure that adequate reliability and validity are obtained from test administration. The issues of standardization, interrater reliability, and procedural reliability are of particular importance. Care must be taken during test administration to control for the potential rater errors of central tendency, standards, halo effect, logical errors, and examiner drift.

For many applications in rehabilitation medicine practice and research, standardized measures have not yet been

developed. Methods derived from single-subject research paradigms provide guidelines for objective measurement when a standardized test is not available. These guidelines, which are discussed in the section “Procedures for Objective Observation and Recording of Behavior” of this chapter, include identifying the behavior to be monitored, operationally defining the behavior, identifying the measurement strategy (e.g., event recording, rate recording, time sampling), establishing interrater reliability, and properly reporting scores and graphing the data.

Specific tests and objective measurement instruments are not discussed because of the number and broad spectrum of measures used by rehabilitation professionals.

The principles discussed in this chapter provide the framework for the readers critically to assess the measures available for their specific application needs. Such critical analysis will further emphasize the need for ongoing development and improvement of objective measures at the disposal of rehabilitation professionals.

# Functional Evaluation and Management of Self-care and Other Activities of Daily Living

## INTRODUCTION

In this chapter, we discuss self-care and activities of daily living (ADL) from the standpoint of rehabilitation across a wide range of ages and conditions. We first describe the importance of this domain of human activity to illustrate why self-care and ADL performance are important rehabilitation goals. We then describe approaches to assessing an individual's ADL skills, sampling the range and scope of assessments in this area that are supported by published research. We attempt to identify best practices and areas of philosophical and procedural controversies. Finally, we turn to the intervention strategies. A collaborative goal-setting process to guide intervention is emphasized. We summarize key intervention strategies across a sample of conditions, citing evidence in support of intervention strategies, where available.

Our objectives in this chapter include

- To familiarize the reader with the central importance of self-care (ADL and IADL) in the life of the patient viewed from the perspective of discharge setting
- To describe a range of approaches toward measuring self-care performance
- To identify strengths and weaknesses of various ADL and IADL assessment instruments
- To describe collaborative goal setting and development of a plan of care
- To review various strategies and principles for intervention within the categories of adaptation, remediation, and compensatory strategies, health promotion, disability prevention, environmental modifications, use of assistive technology devices (ATDs), and use of personal care attendants (PCAs)
- To summarize and research ADL-related interventions and plans of care

Enabling individuals to manage daily self-care is among the most important tasks undertaken by the rehabilitation team. This is because such tasks relate directly to the business of living and their performance signifies a return to participation in the routines of daily life. Self-care tasks include dressing,

eating, bathing, grooming, use of the toilet, and mobility within the home. These are basic tasks included within the general category of ADL. Although able-bodied persons perform most self-care tasks routinely, such tasks can represent difficult challenges for persons with sensory, motor, and/or cognitive deficits.

Other important activities for living in the community are related to managing the requirements of daily life. These extended ADLs (EADLs) go beyond basic self-care and have been labeled by Lawton as instrumental ADL, or IADLs (1). These include food preparation, laundry, housekeeping, shopping, use of the telephone, use of transportation, use of medication, and financial management. Childcare is also an important responsibility in the daily routine of many people.

Unfortunately, there is no consensus on the classification of human activity. As a result, many terms with similar definitions used for ADL categories are used in the medical, health, and rehabilitation literature. Table 9-1 lists some of these. In this chapter, basic ADLs (BADL), such as eating, dressing, grooming, hygiene, and mobility, are described as personal or self-care tasks. Essential tasks for maintaining the living environment and residing in the community are described as IADLs or EADLs (see Table 9-1).

Self-care tasks may assume a symbolic meaning for the individual in a rehabilitation program, because attending to eating, dressing, and toileting tasks is basic part of the routine necessary for establishing a sense of identity (2) as well as for gaining acceptance in a social world (3). This is because appropriate dress, personal appearance, hygiene, and other expectations influence perceptions of the self and others (4).

In the developed nations, about 30% of a typical person's waking hours is spent performing self-maintenance activities, including basic self-care and household maintenance (5,6). For able-bodied persons, an average of more than 1 hour per day is spent in basic self-care activities (7). Research has shown that more than 70% of the variation in discharge decisions following stroke rehabilitation is determined by the ability to function independently self-care tasks necessary for bathing, toileting, social interaction, dressing, and eating (8,9).

**TABLE 9.1** Terminology of Functional Performance

Frequently Used Categories	Activities Typically Included in the Category	Correspondence with ICF Descriptions of Categories and Activities
Self-care	Bathing Communication	Self-care: caring for oneself, washing and drying oneself, caring for one's body and body parts, dressing, eating and drinking, and looking after one's health
Personal care	Dressing Eating	Mobility: moving by changing body position or location, or by transferring from one place to another, by carrying, moving or manipulating objects, by walking, running or climbing, and by using various forms of transportation
Basic ADL (BADL)	Grooming Mobility Toileting (sphincter control) Transfers	Communication: general and specific features of communicating by language, signs and symbols, including receiving and producing messages, carrying on conversations, and using communication devices and techniques
Instrumental activities of daily living (IADL)	Child care Financial management Food preparation	Domestic life: acquiring a place to live, food, clothing and other necessities, household cleaning and repairing, caring for personal and other household objects, and assisting others
Extended ADL (EADL)	Housekeeping Laundry Medication use Shopping Telephone use Transportation use	
Reintegration	Paid Work Volunteerism	Major life areas: carrying out the tasks and actions required to engage in education, work and employment and to conduct economic transactions, including education, work and employment, and economic life
Community participation	Leisure Recreation	Community, social and civic life: the actions and tasks required to engage in organized social life outside the family, in community, social, and civic areas of life, such as participation in spirituality and religion, political life, and citizenship, volunteerism, recreation, and leisure

In the United States, recognition of the importance of functional independence is reflected in population survey data collected by governmental agencies, such as the National Center for Health Statistics (10,11). An individual's functional ability is an important predictor of nursing home placement, with research showing a high correlation between the number of dependencies in ADL and the risk of institutional placement (10,12).

### Self-care and ADL in Context

Current international models of disability consider the multiple factors that influence daily life and the ability to perform necessary life tasks (13). These models recognize the importance of the physical and social settings in which an individual lives, and how these factors come together to support or limit task performance and participation as a member of society. Others with whom an individual regularly spends time constitute that individual's social nucleus, providing important support and social interaction and influencing activity choices and role requirements as well as the level of independence (14–16). This nucleus typically includes friends, acquaintances, and members of the individual's immediate and extended family.

It is within this social situation that the importance of self-care is most apparent, because meeting self-care needs is vital to success in meeting expectations for social interaction. Self-esteem, or the value accorded oneself, is determined by how well self-evaluation matches the values perceived as important in the social environment (17). Self-esteem is influenced by social acceptance and by one's success in achieving a desired social identity (18–21). Because the ability to perform self-care tasks contributes to both acceptance and identity, it can have a direct effect on self-esteem (19,22). Importantly, social factors, including social support, are important predictors of rehabilitation outcome as shown by studies of amputation (23), stroke (24,25), serious burn injury (26), spinal cord injury (20), hip fracture (27).

Typically, self-care activities are taken for granted by the person and society unless difficulties are encountered. Limitations in self-care tasks and dependency on others for their completion serve to diminish an individual's self-concept and can lead to decreased morale and depression (28). A study of elderly patients found that a relationship existed between self-concept and functional independence, and that people who were dependent in ADL scored lower in measures of self-concept (19).

Research has shown a clear relationship among self-concept, morale, and level of functional independence. For example, Chang and MacKenzie found that self-esteem was a consistent and significant predictor of functional ability at various intervals following stroke (20). Chemerinski et al. found that improvements in ADL performance were associated with remission of poststroke depression (21). These studies and others (29) indicate that an important goal of rehabilitation should be to help patients learn to take control of decisions about daily living, since this may contribute positively to their sense of efficacy, morale, and overall sense of well-being. More important, it may also increase life expectancy, since loss of hope and feelings of helplessness during early rehabilitation phases have been shown to be associated with shorter survival rates following stroke (30).

Within living settings, the presence of an individual with needs for care-giving affects the entire family or social group (31,32). When a member of the family can no longer perform expected activities, the daily routine may be upset, creating stress, diminished psychological well-being, and conflict (33). Family members must adjust their expectations of the individual who is disabled as well as adjust to changes in family routines and activities (34).

Family caregivers are important to the well-being of persons with disability and chronic illness (35). Over time families experience stages and time periods, each with characteristic issues. Important concerns related to self-care and care-giving needs must be considered in light of these stages, with recognition that needs change over time. The most significant change affecting caregiving is the number of family members who are available to provide support as a family life cycle matures.

Necessary adjustments made by families or caretakers confronted with rehabilitation challenges often include a reassignment of homemaking tasks or changes in priorities and may impose additional financial or social burdens due to the need to hire outside assistance or rely on volunteers (36). Studies have shown that levels of depression and anxiety, as well as somatic complaints, are more prevalent among caretakers and family members of disabled people living in the home environment than those typically found among members of the general population (33,34). Yeung et al. found that self-confidence in Chinese family carers was an important factor in psychosocial well-being (32). Caregiver burden, a term given to the general strain, isolation, disappointment, and emotional demands of caring for a member of the household with a disability, seems to increase in proportion with ADL needs (37–39). A study of families involved in caring for survivors of stroke found that family adaptation after 1 year was related to family stresses and demands, family resources, and family perceptions. In particular, family functioning was poorer when the patient developed psychological morbidity, when the patient was less satisfied with the recovery, and when the health burden of the stroke was greater (40). In recognition of the increasing importance of the role of household caregivers, interventional strategies, including counseling, education and training, and social support, have been reported. Recent meta-analyses have indicated

that such interventions are effective in improving well-being and mental health and reducing the “burden” of care among caregivers (41,42).

During the rehabilitation process, the family can have a considerable influence on functional outcome (43). A stable and supportive family unit can be of great assistance, whereas families that are functioning poorly can impede rehabilitation. In some cases, poor outcomes can be traced to a lack of family involvement in the rehabilitation process (44). In other cases, too much support can encourage dependency (41). This indicates that the family should be involved in all aspects of rehabilitation, including evaluation and the setting of rehabilitation goals and treatment strategies before and after discharge (45).

A primary source of adjustment difficulties for people with physical disabilities comes from societal treatment of them as socially inferior (46). The common belief that strength, independence, and appearance are important aspects of self-worth is very damaging to people with disabilities. Interaction within a social group often depends on the ability to perform at the group’s expected level; otherwise, the person will not be included as a significant group member (18).

Self-care tasks are not publicly valued in the same manner as gainful employment (47,48). Ironically, they assume importance principally when one’s inability to perform them leads to perceived disadvantage or social stigma (49). Self-reliance in ADL helps to refute the idea that a person with a disability may be a financial or social burden to society. It is important to realize that social participation and quality of life are often the ultimate goals of patients, and this endpoint should influence shared goal setting. Physical health is an enabler of well-being, and the capacity to accomplish self-care represents the beginning set of tasks necessary for participation. As noted by Hogan and Orme, ambulation and self-care mastery alone are insufficient for attaining desired goals related to social participation (50). A research synthesis reported by Bays concluded that independence with ADL, and social support were key variables in the quality of life experienced by survivors of stroke (51). Lund et al. determined that social participation in various activities of life, including self-care, contributed to perceived quality of life in survivors of spinal cord injury (52). Cardol et al. (53) asserted that ethical approaches to planning and implementing care in rehabilitation should place greater emphasis on the autonomy of the individual. This is exemplified by an attentive attitude, opportunities for informed choices by the patient, and consideration for each patient’s preferences, needs, and social contexts (53). In some cases, active participation in goal setting by persons receiving rehabilitation may require special efforts to overcome lack of familiarity, perceived indifference, and other barriers to involvement (54).

### Self-care and Functional Performance

Traditionally, intervention for people who have difficulty performing self-care tasks has begun with training in the acute care or rehabilitation environment. Typically, such intervention includes instruction in procedures to regain dressing,

grooming, hygiene, and food preparation and eating skills. In pursuit of these goals, rehabilitation sessions have been conducted within the patient's hospital room or in simulated ADL settings within the facility. Intervention strategies involve teaching the individual functional skills or the use of assistive technologies so that compensatory strategies can be performed in the postdischarge environment.

Unfortunately, as suggested earlier, ADL training in a rehabilitation facility does not guarantee skill generalization to the discharge location. Patients may perform well in a rehabilitation facility, but skills may not always transfer to the individual's pre-admission or discharge living setting. Environmental and psychosocial factors that directly influence task performance may be too varied between settings for the person receiving rehabilitation to generalize the learned skills (55). In addition, the individual may become dependent on the staff for self-care performance (56) or lack the opportunity to practice new skills on a regular basis. Consequently, performance following discharge may reflect a lack of confidence or motivation.

### **Setting Rehabilitation Goals for the Discharge Environment**

The growing cost of specialized rehabilitation care has led to a reduction in hospital lengths of stay and has resulted in more rapid discharge from special care facilities. More care is now provided in outpatient settings and in the home environment.

This has advantages, since intervention in the home can be beneficial in achieving certain self-care skills and community reintegration (57–59). Community-based intervention has the benefit that the environment can be evaluated in terms of architectural, transportation, and communication barriers and how these support or limit the individual's daily living skills.

### **Collaboratively Planning Self-care and ADL Goals**

Current standards in rehabilitation require the involvement of the person receiving care as well as family members or caregivers, as appropriate in planning intervention (60). Controlled studies have shown that active collaboration in rehabilitation goal setting increases client satisfaction with care (61).

When goals are set in collaboration with the individual receiving care, the motivation to learn and maintain a skill is better than if rehabilitation professionals or caregivers determine the goals. It also appears that agreement on goals may influence functional outcomes by establishing clearer and more realistic goals (62). Each self-care behavior should be evaluated to see if the individual is motivated to learn and maintain it. Some studies have shown differences in the extent to which professionals and persons receiving care have congruent views regarding rehabilitation goals (63) but generally support the value of client participation in decision-making about care (61,64–67). This underscores the need for close collaboration between providers and recipients of care when planning intervention.

One of the first options the professional and person receiving rehabilitation should explore concerning the performance of any self-care task is whether the task is necessary or desired.

The individual may choose not to perform some self-care tasks that were done before his or her illness. For example, a woman with hemiplegia who formerly rolled her hair on rollers on a daily basis may decide to have it cut in an easier-to-manage style rather than learn to use rollers with one hand. This type of decision should be based on individual preferences. Similarly, changes in societal styles and norms may also influence self-care goals, since greater diversity in clothing, hairstyle, and general appearance make it less likely that deviations from the norm will stand out.

In some instances, training procedures can be used to regain a desired skill. Following a cerebrovascular accident (CVA), for example, the therapist may be able to retrain the person to perform the task as it was performed before the CVA if there is sufficient return of voluntary movement. In some instances, the individual may no longer have the perceptual or physical capability to perform a task as before. However, he or she may be able to learn to accomplish the task using different movement patterns or with different body parts.

Environmental changes represent an additional array of intervention options that can be explored by the individual and his or her rehabilitation team as a means of gaining independence in self-care. In some instances, simply rearranging the physical environment may allow the disabled person to perform tasks independently. For example, moving dishes to lower shelves so that the patient can reach them from a wheelchair would represent a modification of the environment requiring only simple rearrangement. Structural changes in the physical environment also may be necessary. These can include major changes such as the architectural modification of rooms to accommodate wheelchair movement or less extensive improvements such as replacing round doorknobs with lever handles for a person who has weak grasp or installing bathroom rails and grab bars for persons with unsteady gait or balance difficulties.

The idea of universal design, which describes key principles for making environments, facilities, and objects useable for people regardless of their physical attributes or limitations, should have a positive impact on reducing barriers to activity and participation in the years ahead (68). This emerging environmental movement is broader than previous concepts of environmental accessibility (as described in the Americans with Disabilities Act and other legislation), yet highly relevant to rehabilitation and disability. Universal design emphasizes creating environments and objects that are simple and intuitive and that enable equitable and flexible use, have perceptible forms of information, require low physical effort, have tolerance for error, and have sizes and shapes appropriate for approach and use.

Assistive technology devices (ATDs) can be used to aid in the satisfactory performance of a desired task. These devices can range from simple, inexpensive articles, such as bathtub seats, to the use of expensive equipment such as computers for environmental control and communication (69). Many labor-saving devices are now widely available in catalogs and retail outlets catering to the general population. A line of fashionable apparel

designed for easy dressing and maintenance is now available for persons with limitations in range of motion. The rehabilitation professional's role is to inform the patient of the existence and cost of these devices and to train the individual and caregiver in their use and maintenance.

Assistance from other people for the partial or total completion of a desired task is another option available to the individual receiving care (70). Assistance may come from spouses, friends, or paid PCAs. The role of the professional in this case must be to instruct the individual and/or the care attendant on optimal approaches to working together for the completion of identified self-care tasks (71). Figure 9-1 provides a decision chart that describes the process of goal setting summarized in this section.

Collectively, the personal and environmental intervention options described in this section form the basis for collaborative decision-making and treatment planning. It should be borne in mind that neither diagnosis alone nor the extent of impairment can serve as an adequate basis for planning self-care intervention. Together, the rehabilitation team and the individual receiving care must determine those approaches that represent the most realistic and achievable goals based on

the abilities, values, and personal social circumstances of the recipient of care (61). Only in this way will optimal results be achieved after discharge.

## ISSUES IN ADL EVALUATION

Granger (72) defines functional assessment as “a method for describing abilities and limitations and to measure an individual's use of the variety of skills included in performing tasks necessary to daily living, leisure activities, vocational pursuits, social interactions, and other required behaviors.” Assessment must take place within a conceptual framework. An early model for this purpose was the World Health Organization's International Classification for Impairment, Disability, and Handicap (ICIDH) (73). The ICIDH was revised in 2001 after an international revision effort, and is now called the International Classification of Functioning, Disability, and Health, or ICF (13). The ICF and its revised classification broadens the overall scope of the structure to include categories that view limitations to activities and participation as functional

**FIGURE 9-1.** Decision-making process for self-care/ADL intervention.

**TABLE 9.2** International Classification of Functioning, Disability and Health, World Health Organization, 2001

	Part 1: Functioning and Disability		Part 2: Contextual Factors	
	Body Functions and Structures	Activities and Participation	Environmental Factors	Personal Factors
Domains	1. Body functions 2. Body structures	Life areas (tasks, actions)	External influences on functioning and disability	Internal influences on functioning and disability
Constructs	Change in body function (physiological) Change in body structures (anatomical)	Capacity Executing tasks in a standard environment Performance Executing tasks in the current environment	Facilitating or hindering impact of features of physical, social, and attitudinal world	Impact of attributes of the person

Adapted from World Health Organization (2001). *International Classification of Functioning, Disability and Health*. World Health Organization. Available at: [www.who.int/icidh/ICIDH](http://www.who.int/icidh/ICIDH)

consequences that are influenced by environment, personal factors, and problems with body function or structure. The ICF also addresses concerns about terminology (such as use of the word *handicap*) and adopts terms and definitions that are global in application and reflect differences between developed and underdeveloped nations. The revised model for the ICF now has two parts, each with two components with defined domains and constructs as reflected in Table 9-2.

As a conceptual framework for considering self-care, the ICF provides a means for recognizing that self-care tasks take place within particular living environments and may be performed differently based on an individual's habits, culture, and social situation. This chapter attempts to emphasize that these contexts should be reflected in the functional assessment process, the determination of rehabilitation goals, and the type and location of interventions chosen.

Assessment has, as its ultimate purpose, the ability to make informed decisions. Scales and instruments designed to assess the ability of the individual to perform self-care tasks may assist in intervention or discharge planning by describing or documenting current abilities or monitoring changes in functional status. More global scales, which may include self-care components, are used to provide information on the effectiveness of rehabilitation programs, thus playing an important role in program evaluation.

### Historical Development of Self-care Evaluation Tools

Assessment of the individual's ability to function independently has been conducted in medical rehabilitation for nearly 50 years. In an early review of the problems of measurement and evaluation in rehabilitation published in 1962, Kelman and Willner found that poorly conceptualized outcome criteria, lack of standardization, disagreement about methods, multidimensional scales, and the influence of the setting on performance were barriers to effective management (74).

In the ensuing two decades, several published reviews of functional assessment from the standpoint of relevance, clinical utility, scale construction, standardization, reliability, and validity of scales concluded that the development of new scales should be curtailed, with greater effort devoted to the refinement and validation of existing scales (75–79). The challenges of functional assessment are summarized in the following sections.

### Determining Capability Versus Characteristic Behavior

Current models of rehabilitation emphasize that function cannot be considered in isolation from its environmental context. This is made especially clear by the distinction between capability and actual behavior. Measures of capability represent what the person can do, whereas measures of actual behavior indicate what the person does.

Many self-care assessments in use during the past 30 years have been designed to measure what a patient is capable of doing within the care facility. An assessment of actual behavior, however, should ideally take place in the daily living environment in which the person will be performing the tasks. The setting influences actual performance that may differ from the individual's capability. Awareness of the distinction between capability and actual behavior and their relationship to the patient's environment has had an important impact on the development of new approaches to the assessment of self-care abilities. The ICF is based on a premise that disability is the result of an interaction between the person's physical capabilities and the characteristics of a setting or environment. Environments have characteristics that can support or interfere with performance. It seems appropriate then that self-care performance assessment, if it is to be accurate and complete, should consider both the person's physical capabilities and the characteristics of the environment.

As clients return home from hospitals, units, or residential facilities at an earlier stage, ease of administration becomes an

issue for determination of client progress. Although one way of determining ability is through observation of performance, another approach involves asking individuals themselves (or people living with them) to provide verbal reports. The literature is mixed about the validity of such reports. A study of stroke survivors by Knapp and Hewison found that caregivers generally perceived stroke survivors as more functionally impaired than did the survivors themselves (80). In contrast, a study by Wilz found that stroke survivors were able to accurately assess their level of impairment (81). Confusing the issue further, a study by Kwakkel et al. demonstrated that physical and occupational therapists consistently underestimated the degree of independence in ADL and level of recovery achieved by patients undergoing rehabilitation following stroke (82). The point here is that the most accurate way to measure self-care performance is through actual observation of the individual within the performance environment. Even then, however, the maintenance or consistency of the individual's performance over time will be unknown.

### Contextual Factors in Self-care Evaluation

A complete assessment of self-care function should consider factors that include the patient's ability to manage devices that extend independence through environmental control; the family resources available to the patient in the environment to which he or she is to be discharged; the amount of time or energy required to perform tasks independently; and the degree of safety with which patients are able to perform tasks.

Developments in high technology for independent living have made it possible to assess people with severe disability in terms of their available movements and physical resources for controlling switches to activate environmental control units. Paradoxically, these devices are more likely to extend the patient's ability to perform IADL more proficiently than self-care tasks.

The inability to perform self-care tasks independently, of course, does not require discharge to institutional care if human resources are available in an alternative environment. Frequently, the client can, and does, rely extensively on the assistance of a partner, other family members, or friends, or PCA to assist with self-care tasks. It can be argued that the presence of these resources, although commonly determined by the social worker in planning discharge, should be given early consideration in planning rehabilitation intervention.

Additional contextual considerations include the amount of time and energy required to perform the task independently versus the value of the task as perceived by the patient. It cannot be assumed, given competing requirements for time and energy, that all patients assign the independent performance of all self-care tasks the same degree of importance. Thus, the motivation to complete the task independently after discharge is likely to be a function of the alternatives available for task completion, the importance of the task to the patient, and the amount of time and energy required to perform the task independently in the face of competing demands.

Weingarden and Martin reported on a study of ten postdischarge spinal cord-injured patients to determine if time was a factor in the decision to retain, modify, or completely delegate dressing activities (83). Although all ten patients were capable of dressing independently at home, none did so routinely. The authors concluded that the person's concepts of appropriate time and energy expenditure are important considerations in postdischarge decisions on the use of functional skills. Another study by Pentland, Harvey, and Walker explored time use by 312 men with spinal cord injury living in the community. Their study showed that the level of the lesion, the level of functional independence, and the setting did not predict the amount of time spent in personal care, productivity, leisure, and sleep. Nor did the time spent in these activities predict outcomes such as life satisfaction, perceived health, or adjustment to disability (84).

The degree of safety with which a task is performed may be of obvious importance to the practitioner but may not be apparent to the patient or those caregivers in the environment who may be providing assistance with self-care tasks. It is, therefore, important that training in self-care assistance be provided as part of the rehabilitation effort and that the ability of helpers to render this assistance in a safe and effective manner be assessed before the patient is discharged (85).

### Defining Functional Outcomes

Many observers have noted that increased emphasis on accountability and the need for determining the benefit-cost ratios of rehabilitation have revealed ambiguities and a lack of consensus regarding definitions of rehabilitation success. For example, gains in self-care ability, although important to the patient, may not be perceived as beneficial within a system that perceives employability as the sole criterion of success. This has created additional pressure for the development of evaluation tools that consider post-discharge function in the living setting.

Fortunately, increased attention to these issues has resulted in increased research, which has encouraged the refinement or development and validation of several scales that assess self-care performance. Some of these scales possess characteristics suitable for program evaluation and research as well as clinical decision-making. The need remains, however, for greater awareness of the problems associated with functional assessment, greater consensus on appropriate measurement items, and consistency in definitions and terminology. Although awareness of the importance of using instruments that possess necessary measurement characteristics has improved, a tendency to create *ad hoc* instrument modifications continues, making comparisons between studies more difficult.

### Approaches to Obtaining Performance Data

Functional evaluation can be accomplished by direct and indirect means. Direct evaluation involves first-hand observation of skill performance. Judgment based on subjective observation, however, is not always an accurate predictor of outcome (82). Indirect evaluation can be done by using client report

(gathered through mailed surveys, face-to-face or telephone interviews) or reported by proxies, such as members of the family or household. Evidence of the validity of such indirect approaches is equivocal (80).

In addition to creating threats to reliability, indirect reporting of functional performance can create threats to validity. A number of factors make it difficult to establish the validity of functional ability indices. These can include the impact of assistive technologies, environmental differences, and caregivers. Psychological factors, such as the patient's level of motivation, the professional perspective of the rater, and the role expectations of the patient can compromise efforts at establishing the validity of these scales (86). There are also sources of error in observation, including the likelihood that the client's performance is influenced by the evaluation process and therefore may not represent a typical or consistent performance.

### Desirable Attributes of Self-care Scales

Reviews of functional status measures have identified several criteria for evaluating the quality or suitability of scales.

These criteria derive both from psychometric standards and from expert opinion, and include psychometric properties of validity, reliability, sensitivity to change, and methods for assessing scaling properties, such as Rasch analysis (87,88). Psychometric standards in the United States have been greatly influenced by the jointly developed standards of the American Psychological Association, the American Educational Research Association and the National Council on Measurement in Education (89). Within rehabilitation, the American Physical Therapy Association (APTA) (90,91) published measurement standards in 1991, and the American Congress of Rehabilitation Medicine developed Measurement Standards for Interdisciplinary Medical Rehabilitation in 1992 (92). These standards provide important guidelines for the appropriate use and interpretation of measures, including self-care scales. They also provide definitions of important terms relevant to test development, and refer to technical problems that should be avoided by developers and users. Table 9-3 summarizes important characteristics that can be used in evaluating, comparing, and selecting rehabilitation measures.

**TABLE 9.3** Desirable Criteria in Rehabilitation Measures of ADL Performance

Criterion	Explanation
Standardization	Scale has explicitly stated procedures for administration and scoring, performance data from a normal population, preferably of varying ages; information on the measurement properties of the scale (e.g., its computed reliability); and a statement of the necessary qualifications of the examiner. It is difficult to standardize scales that are useful both as measures of capability and as measures of actual functioning, because of varying contextual factors.
Scalability	Scaling procedures serve to quantify a person's responses to a defined set of tasks so that they are distributed along a Continuum of performance. For an assessment device to be considered a true scale, it must be established that the tasks performed will cumulatively yield a score or descriptor that represents increasing capability or independence.
Reliability	An acceptable scale should provide a reliable measure of the client's level of performance. Reliability refers to a scale's accuracy and consistency in providing information, regardless of the time, setting, or person performing the assessment. Scales that have carefully defined methods and scoring criteria are likely to be more sensitive and consistent, and present a more accurate picture of the client than those that do not.
Validity	Validity is related to theoretical and methodological issues and depends on a number of factors. These include the extent to which the scores on the assessment are related to some external criterion, the degree to which the instrument contains items or tasks that represent the domain of interest, and the relationship of the instrument to other measures that collectively support various theoretical assumptions. A scale cannot be valid if it is not reliable.
Comprehensive	Self-care assessments are more useful if they determine performance levels for all BADL skills and are applicable to every diagnosis. Because clients have the universal need to perform or have performed for them basic self-care tasks, broad applicability is appropriate and facilitates comparison of research findings among differing client groups. To the extent that extended ADLs can be assessed, a scale becomes more useful as a measure of independence in everyday situations.
Performance based	This characteristic eliminates measurement error due to selected observations or inaccurate memory. Although self-care abilities are increasingly being evaluated through interviews and surveys, this is most advisable only after discharge and if validation of such approaches has been demonstrated. Although performance-based scales should not emphasize speed, time can become an issue if the extent of time required makes it impractical.
Practical	The extent to which a scale is designed to facilitate decision-making and research is an important consideration in instrument selection. The number of items should be sufficient to permit reliability while requiring a reasonable length of time (i.e., 30–45 min) for administration. To the extent possible, items should not require equipment that would unduly limit locations where the scale could be administered. Scoring sheets should contain clear explanations of criteria and should be designed to permit accurate recording as well as coding for data processing. Terminology should be readily understandable, with abilities expressed using everyday language. The meaning of scores should clearly convey a client's level of functional independence to professionals and caregivers who will be living with the client.

### Resolving Measurement Problems in Functional Evaluation

A topic of considerable importance in the area of functional assessment is that of how numbers are assigned to performance observations and later interpreted. Most self-care scales use ordinal rankings to assign numbers to patient performance on selected items. Merbitz et al. (93) identified the limitations of such rankings, based on the characteristics of ordinal measurement scales. They pointed out that the properties of ordinal scales do not permit valid conclusions to be drawn on the summed or averaged scores obtained from them and that their misuse in this way is misleading and subject to invalid inferences. Further, because they are given equal weight in scoring, the implied assumption of most scales of functional ability is that the items being measured are equally important, either to the professional or to the individual being measured. This is clearly an invalid assumption.

Using techniques developed by Rasch (94) and others, however, observations of functional ability (from items and persons) can be translated into linear measures. The logit unit of measurement produced by the Rasch model is the natural log of the odds of a correct response. This transformation allows the researcher to interpret the person and item information using the same units of measure. Once the scores for the persons and items have been transformed using Rasch scaling, other information about the persons and items can be obtained using a variety of statistical methods. These transformed scales possess the properties necessary for valid inferences (95). In effect, these statistical transformations lead to scores, which are corrected for differences in items or raters. Such techniques are increasingly being applied to existing scales (96).

### Patient Collaboration in Evaluation and Goal Setting

No discussion of functional evaluation is complete without a consideration of the values that may be reflected in the process. Although functional assessment is a judgmental process, it should not be unnecessarily value laden. In fact, the rehabilitation goal of independent functioning itself reflects a societal value not shared to the same extent by all cultures. There are profound differences in the cultural heritages and life experiences of individuals, and these differences bring differing sets of values about independence and self-care to the rehabilitation setting. Effective management of the client requires an appreciation of these value differences, and an appreciation that interdependence rather than independence is a condition typical of societal groups. It is, therefore, important for the overall functional evaluation to include methods for determining premorbid activity patterns and leisure interests as well as values and attitudes toward assistance. Characteristic methods for performing BADL and EADLs, as well as the characteristic aspects of the environment in which these have been performed, are important information in planning successful intervention strategies for management of personal care and other ADL necessary for life satisfaction and quality.

### Selected Measures of Basic ADL (Self-care)

Although dozens of instruments designed to assess personal or self-care performance have been reported in the literature, consensus has not been achieved for use of a single scale. Scales range from those that focus on personal or self-care ADL skills (BADLs) to those that focus on IADL or EADL skills. Still others are more global and include physical functioning and/or more EADL skills (Table 9-4). These have been called *global scales*.

One such global scale is the Functional Independence Measure (FIM). The past decade has shown a marked growth in the use of the FIM developed in the United States by Granger et al. (72) in the 1980s and now translated into several languages. The FIM and its associated measurement systems have been adopted as a key part of decisions influencing public funding of rehabilitation services in the United States. The FIM has not been embraced universally, however, and the Barthel Index (BI), developed by Mahoney and Barthel (97), with its modifications, continues to be used extensively throughout the world.

Besides the BI and the FIM, a handful of scales have demonstrated sufficient validity and frequency in the literature to warrant their review here. This review is not intended to be exhaustive, and it is acknowledged that there are other measures with self-care components that have been developed or are in use for specialized purposes that are not described here. To gain a complete picture of the client's level of function and community reintegration within the new WHO (ICF) framework requires that items pertaining to household maintenance and community functioning also be considered. For this reason, additional items relating to household and community functioning often accompany the assessment of basic self-care items. In studying the association between the three widely used measures of functional change (FIM, BI, and Functional Assessment Measure [FAM]) and core sets of statements representing the domains of the ICF, Grill et al. concluded that many aspects of human functioning are not measured, making it necessary to add supplementary measures (98).

The following paragraphs report the composition, measurement properties, and scoring of several scales. Brief summaries of selected studies describing their use with varying client populations are also provided. Where available, evidence reporting reliability and validity is summarized. The scales to be reviewed in this section are the BI, the Katz Index of Independence in ADL (99), and the FIM (100).

#### The Barthel Index

In 1965, Mahoney and Barthel published a weighted scale for measuring BADL in disabled patients (Table 9-5) (97). The initial BI included ten items, including feeding, transfers, personal grooming and hygiene, bathing, toileting, walking, negotiating stairs, and controlling bowel and bladder. Items are scored differentially according to a weighted scoring system that assigns points based on independent or assisted performance. For example, a person who needs assistance in eating

**TABLE 9.4 Measures of ADL/IADL**

Assessment Tool	Authors/Year of Publication	Type	Description
Arnadottir (A-1) OT-ADL Neurobehavioral Evaluation	Arnadottir (1990)	Observation (late adolescent-adult)	This instrument is an observational tool used to look at neurobehavioral deficits through observation of self-care activities such as feeding, grooming, dressing, transfers, and functional communication
Assessment of Motor and Process Skills (6th ed.)	Fisher (2006)	Observation (children and adult)	The original version of this instrument was designed to assess motor process skills through observation of 16 ADL motor and 20 ADL process skills. There is also a school version of the AMPS
BI of ADL	Mahoney and Barthel (1965) reliability studies and updates since then	Verbal report/observation (adult)	This assessment addresses ten ADL areas including feeding, bathing, grooming, dressing, bowel and bladder control, toilet use, transfers, mobility, and stair climbing
Behavioral Assessment Scale of Oral Functions in Feeding	Stratton (1981)	Observation (children)	This tool examines a child's feeding skills including items such as lip closure, tongue control, sipping, etc. Children are rated on a scale ranging from passive response to active participation
Canadian Occupational Performance Measure (4th ed.)	Law et al. (2005)	Interview (children and adults)	Individualized client-centered interview evaluating self-perception, may be used with an older child, or in conjunction with a caregiver
Child Occupational Self-Assessment (version 2.1)	Keller et al. (2005)	Self-rating scale (children)	The child version of the Occupational Self-Assessment uses happy faces and stars to facilitate child self-evaluation of perceived occupational competence in a variety of occupational areas
Frenchay Activities Index	Holbrook and Skilbeck (1983)	Self-report with recording form (adults)	Although originally developed for clients with stroke, this tool has been expanded to other users. Guidelines for scoring include descriptions of examples in each area, and amount of client involvement in doing the activity
Functional Assessment Measure	Hall (1997)	Used in conjunction with the FIM	This tool was designed by clinicians in order to be used along with the FIM. The tool addresses cognitive, behavioral, communication, and community functioning measures
Functional Evaluation for Assistive Technology	Raskind and Bryant (2002)	Checklist/observation and Interview (children and adults)	This evaluation takes an ecological approach using five scales to determine appropriate assistive technology for the client
FIM (The Center for Functional Assessment Research at SUNY, Buffalo, 1999)	The Center for Functional Assessment Research at SUNY, Buffalo, 1999	Observation/history taking (adults; child's version available as well)	This tool is an 18-item ordinal scale encompassing seven levels designed to identify areas of dysfunction and function in self-care
FIM for Children WeeFIM II	Hamilton and Granger (2005); Center for Functional Assessment Research, 2005	Observation/history taking (children)	The WeeFIM was recently updated to the WeeFIM II and now includes a module for 0–3 in addition to the tool for older children. The original WeeFIM consists of 18 items assessing self-care, motor and cognition—this is designed to measure the amount of caregiver assistance needed. The 0–3 module measures motor, cognitive, and behavioral performance
Independent Living Scales	Loeb (1996)	Observational (adults)	The ILS tool is designed to assess cognitive skills necessary for independent living. Five scales include memory/orientation, managing money, managing home and transportation, health and safety, and social adjustment

**TABLE 9.4** Measures of ADL/IADL (*Continued*)

Assessment Tool	Authors/Year of Publication	Type	Description
Instrumental Activities of Daily Living Scale (IADLS)	Lawton and Brody (1969)	Client/practitioner interview/survey (adults)	This interview-based tool covers eight daily living tasks including use of phone, shopping, food preparation, housekeeping, laundry, transportation, medications, and finances. As with many self reports or interviews, the utility of the tool depends on the reliability/insight of the client, or familiarity of the practitioner with the client's functioning level
Katz Index of ADL	Katz et al. (1963, 1970)	Interview/observation (adults)	Short assessment/index of ADL function including bathing, dressing, toileting, continence, transferring, and feeding
Klein Bell Activities of Daily Living Scale	Klein and Bell (1982)	Observational rating scale (children and adults)	This scale considers ADL items in six different functional areas including dressing, elimination, mobility, bathing, hygiene, eating, and emergency/phone
Kohlman Evaluation of Living Skills (3rd ed.)	Kohlman Thomson (1992)	Observation/interview (adults)	Typically designed for the psychiatric population, some studies have expanded beyond this area. The tool rates clients in ADL areas including self-care, safety and health, money management, transportation and telephone, and community skills
Melbourne Low Vision ADL	Haymes et al. (2001)	Observation (adults)	This test is designed for persons with low vision and assesses current function and rehabilitative outcomes in ADL. The assessment uses both client interview and direct observation
Melville-Nelson Self-Care Assessment	Nelson and Melville (2002)	Observational rating scale (adults)	This rating scale looks at client function in personal self-care ADL of bed mobility, transfers, dressing, eating, toileting, personal hygiene, and bathing
Milwaukee Evaluation of Living Skills	Leonardelli (1988)	Observation (adults)	This evaluation was originally designed for the psychiatric population but is also used in psychiatric medical units. The evaluation consists of 20 subtests that may be used in their entirety or in any combination deemed appropriate to the client needs. Skill areas include areas such as communication, bathing, dressing, eating, hair care, safety in the home and community, use of money, etc.
Nottingham Extended Activities of Daily Living Index	Nouri and Lincoln (1987)	Self-report questionnaire (adults)	This evaluation is another self report instrument that measures 21 tasks in four areas including mobility, kitchen tasks, domestic tasks, and leisure
Performance Assessment of Self-Care Skills (version 3.1)	Rogers and Holm (1994)	Observational rating scale (adults)	This instrument measures ADL and IADL in either the clinic or home (two versions). Scales address functional mobility, personal care, physical IADL, and cognitive IADL
Pediatric Evaluation of Disability (PEDI)	Haley et al. (1992)	Observation/inventory and interview (children)	The PEDI is a widely used standardized tool to measure function in children with disabilities age 6 mo to 7.5 y but has been applied to older children who have conditions placing them in a developmental functioning level lower than their age. Domains assessed include self-care, mobility, and social function
Refined ADL Assessment Scale	Tappen (1994)	Observational rating scale (adults)	This observational scale assesses five ADLs including toileting, washing, grooming, dressing, and eating. The scale is designed to be used in the natural morning routine and outcomes indicate the level of assistance needed
Safety Assessment of Function and the Environment for Rehabilitation (SAFER)	Oliver et al. (1993) and Chu et al. (2001, 2002)	Interview/observational checklist (adults)	This scale consists of questions divided into areas including ADL, addictions, and personal behaviors. Areas assessed are designed to look at current function and provide a baseline for future assessment.

would receive five points, whereas independence in eating would be awarded ten points. A client with a maximum score of 100 points is defined as continent, able to eat and dress independently, walk at least a block, and climb and descend stairs. The authors were careful to note that a maximum score did not necessarily signify independence, since IADLs such as cooking, housekeeping, and socialization are not assessed.

The BI may be the most widely studied and used self-care scale globally. Several studies have shown that the scale has acceptable psychometric properties, including that it is

sensitive to change over time, that it is a significant predictor of rehabilitation outcome, and that it relates significantly with other measures of client status. Granger et al. reported the stability (i.e., test-retest reliability) of the BI as 0.89, whereas interrater reliability coefficients were above 0.95 (100). One study of interrater reliability between nursing staff and non-clinical research assistant showed that although an overall agreement was within acceptable boundaries, two items out of ten showed weakness for agreement (transfer and dressing) (101). Schlote et al. found that the BI had excellent reliability, including the

**TABLE 9.5** BI Items and Scoring Weights

	With Help	Independent
1. Feeding (If food needs to be cut = help)	5	10
2. Moving from wheelchair to bed and return (includes sitting up on the bed)	5–10	15
3. Personal toilet (wash face, comb hair, shave, clean teeth)	0	5
4. Getting on and off toilet (handling clothes, wipe, flush)	5	10
5. Bathing self	0	5
6. Walking on level surface (or, if unable to walk, propel wheelchair)	10	15
	0 <sup>a</sup>	5 <sup>a</sup>
7. Ascend and descend stairs	5	10
8. Dressing (includes tying shoe laces, fastening fasteners)	5	10
9. Controlling bowels	5	10
10. Controlling bladder	5	10

<sup>a</sup>Score only if unable to walk.

A client scoring 100 BI is continent, feeds himself, dresses himself, gets up out of bed and chairs, bathes himself, walks at least a block, and can ascend and descend stairs. This does not mean that he is able to live alone; he may not be able to cook, keep house, and meet the public, but he is able to get along without attendant care.

From Mahoney FI, Barthel DW. Functional evaluation: the Barthel index. *Md State Med*. 1965;14:61–65.

correspondence of scores between physician and nonphysician raters of the status of stroke survivors (102), while Green et al. found that the BI had excellent test-retest reliability (103) using a similar population. Shortened versions of the BI (BI-3 and BI-5) have also been developed, and these have shown evidence of satisfactory psychometric characteristics and predictive validity acceptable for outcome use (104,105).

The initial BI score was found to be the most reliable predictor of final rehabilitation outcome in the study of stroke patients conducted by Hertenstein et al. (106). This study concluded that the BI was a more reliable predictor of rehabilitation outcome than estimates based on computed tomography showing the extent of the lesion after CVA. The BI also has been found to correlate significantly with the type of discharge and shorter length of stay for patients with CVA (107,108) and independent living outcome for patients with spinal cord injury (109), as well as participation of young adults with disabilities (110). Scores on the BI and the PULSES Profile have been shown to correlate substantially (111), as have scores on the BI and the physical subscales of general health status measures such as the SF-36, the Sickness Impact Profile, and the Dartmouth Functional Health Assessment Charts (112). Other studies have similarly provided evidence of concurrent validity with other measures of ADL (113,114). In a clinical trial of stroke rehabilitation, van Hartingsveld et al. used Rasch analysis to weigh item scores of the BI and found improvement in determining results (114,115). Bowel and bladder items emerged as having the poorest fit in analyzing outcomes. Some studies have reported both floor and ceiling effects when the BI is used (113,116–118) or have questioned its utility in trials of outcomes with particular disease groups (119) or have recommended its use in the sub-acute phases of recovery (120). Development of a self-rated BI for use by stroke survivors living at home has been reported as demonstrating acceptable reliability for practical use (121).

A modified version of the BI and the extended BI (EBI) (122), was developed to address the perceived limitations of the FIM and existing BI by adding items for comprehension, expression, social interaction, problem solving, memory/learning/orientation, and vision/neglect. Separate studies of large groups of neurologic patients have shown that the EBI is a reliable, valid, and practical instrument that is sensitive to changes over time (122–124). Because of the manner in which the new items are administered, rater training is necessary. Time required to administer the EBI was described as significantly shorter than the time needed to administer the FIM.

### The Katz Index of Independence in ADL

The Katz Index of Independence in ADL was developed to study results of treatment and prognosis in the elderly and in those with chronic illness (125). Development of the index was originally based on observations of a large number of activities performed by a group of patients with fracture of the hip.

The index is based on an evaluation of the functional independence of patients in bathing, dressing, going to the toilet, transfers, continence, and feeding. Using three descriptors for rating independence in each of the six subscales, the rater is able to derive an overall grade of independence with the aid of specific rating criteria. Depending on the determined level of independence, a client is graded as A, B, C, D, E, F, G, or Other. According to the scale, a client graded as A would be functioning independently in all six functions, whereas a client graded as G would be dependent in all rated functions. Patients graded as “Other” are dependent in at least two functions but not classifiable as C, D, E, or F. Through observations over a defined period of time, the observer determines whether the client is assisted or whether the client functions on his or her own when performing the six activities. Assistance is classified as active personal assistance, directive assistance, or supervision.

In studies of the Katz Index involving more than 1,000 patients, the scale was found to result in an ordered pattern, so that a person able to perform a given activity independently also would be able to perform all activities done by those graded at lower levels (99). This hierarchical structure correctly classifies the functional ability of patients 86% of the time and reflects a desirable property of scalability (126).

The Katz Index of Independence in ADL has been used as a tool to accumulate information about recovery after CVA (127–129) and amputation from peripheral vascular disease (130), as a means of providing information about the need for care among patients in late poliomyelitis (131,132), following hip fracture (133,134), in persons with dementia (135–137) and as an instrument to study information about the dynamics of disability in the aging process (138–140). Brorsson and Asberg used the scale in a study of internal medicine patients in a general hospital in Sweden (141). Their study found a high degree of interrater reliability and high coefficients of scalability. Reijneveld et al. have also reported successful use of the Katz scale with Dutch, Turkish, and Moroccan populations (142).

### Selected Measures of IADL

Increasingly, as rehabilitation professionals give greater attention to the functional context of the client, more consideration is being given to IADLs, or the individual's ability to perform those tasks beyond basic self-care necessary to live in the community. Wade (143) has suggested that these types of ADLs be described as extended activities of daily living (EADL). Other terms in use for similar scale items are social ADL and advanced ADL (144).

In this section, several scales that focus specifically on IADL (EADL) performance are reviewed, including the Assessment of Motor and Process Skills (AMPS), the Nottingham EADL Scale, and the Frenchay Activities Index (FAI). These scales are chosen because of their global use and the availability of published studies of their reliability and validity.

### Assessment of Motor and Process Skills

The AMPS is an observational evaluation that is used to simultaneously examine both the ability to perform IADL and the underlying motor and process capacities necessary for successful performance (145). The AMPS is an assessment system that requires a clinician to observe a person performing IADL as he or she would normally perform them. The individual to be measured selects two or three familiar tasks from among more than 50 possibilities described in the AMPS manual. After the observation, the clinician rates the person's performance in two skill areas: IADL motor and IADL process. Table 9-6 lists the motor and process areas. Motor skills are defined as observable actions that are supported by underlying abilities, including postural control, mobility, coordination, and strength. The AMPS motor items represent an observable taxonomy of actions used to move the body and objects during actual performance. Process skills reflect the organization and execution of a series of actions over time in order to complete a specified task. Thus, process skills may be related to a person's underlying attentional, conceptual, organizational,

and adaptive capabilities. Like the AMPS motor skill items, the AMPS process skill items represent a universal taxonomy of actions that can be observed during any task performance.

During each IADL task performed for the assessment, and for each of the 16 motor and 20 process skills (see Table 9-6), the person is rated on a four-point scale: 1 = deficit, 2 = ineffective, 3 = questionable, and 4 = competent. The raw ordinal scores are analyzed using the Rasch approach referred to as many-faceted Rasch analysis. This approach rests on a mathematical model of likelihood that the person will receive a given score on each of the motor and process skill items. The observed counts of the raw scores of IADL motor and process skill items constitute ordinal (ranked) data. These counts are converted by logistic transformation into additive, linear measures. Once the raw scores are computer analyzed, the derived person ability measures (motor and process) become estimates of the person's position on the two AMPS scales. That is, the AMPS motor and process scales represent continua of increasing IADL motor or process skill ability, and the person's estimated position on the AMPS motor and process scales, expressed in logits, represents his or her IADL motor and process skill ability (145).

The many-faceted Rasch analysis used in the AMPS allows simultaneous calibration of three aspects of performance: item

easiness, task simplicity, and rater leniency. Each of these item characteristics is determined by using a probabilistic model. The ability measure produced by the Rasch analysis is the estimated person ability plotted on a linear scale and is defined by the skill item easiness and task simplicity but adjusted for the rater who scored the task performance (151).

Because the person ability measures on the AMPS are adjusted for task simplicity, a clinician can use the ability measure to predict whether a person possesses the motor and process skills necessary to perform tasks that are more difficult than those the person was observed performing. Also, since the AMPS includes 50 possible IADL tasks and each person is observed performing only two or three, the number of possible alternative task combinations is very large. Regardless of how many different tasks the individual performs, however, the ability measure will always be adjusted to account for the ease and simplicity of those particular tasks, so direct comparisons can be made among persons even though they performed completely different tasks.

Several investigations using the AMPS with persons who have psychiatric (146) orthopedic, neurologic, cognitive (147,148), and developmental disabilities (149,150) have been reported. The ability of the AMPS to enable analysis of the separate contributions of motor and process variables has provided support for theoretical assumptions about the specific variables contributing to task limitations in various conditions. Validity studies have suggested that the AMPS can

help predict home safety (151) and measure improvements following intervention in psychiatry (152–155), developmental disabilities (156); multiple sclerosis (157,158) and stroke (159–162); and acquired brain injury (163,164), cerebral palsy (165,166), dementia (167–172), and in students with difficulties interfering with function in school (173–175). The AMPS has demonstrated consistency across gender (176), raters (177), settings (149), and different cultural groups (178,179). These investigations have established the reliability (180) and validity of the AMPS. The AMPS approaches the assessment of functional performance using many-faceted Rasch analysis, with clients selecting the item to be performed from an inventory of possible IADL items.

### The Nottingham EADL Index

The Nottingham EADL Index (NEADL) was developed by Nouri and Lincoln (181) in 1987 and is widely used throughout Europe and in other countries. This self-report scale has 21 items organized into four sections, which can serve as subscales. The sections include mobility, kitchen tasks, domestic tasks, and leisure activities. Scoring is along a four-item range of discrete categories, ranging from not done at all to done alone easily. Unfortunately, there are no guidelines for assigning scores. Because of the range of EADL tasks reported, the scale has intuitive appeal as an outcome measure of rehabilitation and social participation. Table 9-7 lists specific items included in the Nottingham EADL.

**TABLE 9.7** Nottingham Extended ADL Index

Answers	Not at All	With Help	Alone with Difficulty	Alone Easily
Mobility Questions—Do you:				
Walk around outside?				
Climb stairs?				
Get in and out of the car?				
Walk over uneven ground?				
Cross roads?				
Travel on public transport?				
In the Kitchen—Do you				
Manage to feed yourself?				
Manage to make yourself a hot drink?				
Take hot drinks from one room to another?				
Do the washing up?				
Make yourself a hot snack?				
Domestic Tasks—Do you:				
Manage your own money when you are out?				
Wash small items of clothing?				
Do your own shopping?				
Do a full clothes wash?				
Leisure Activities—Do you:				
Read newspapers or books?				
Use the telephone?				
Go out socially?				
Manage your own garden?				
Drive a car?				

A growing literature on use of the Nottingham scale is beginning to demonstrate that it is a suitable instrument for evaluating EADL function in the community. Although most reported studies involve subjects who have received rehabilitation following stroke (182–184), the measure has been used with other diagnostic groups such as those with pulmonary problems (185–187), elderly persons in the community (188,189), and patients with hip replacement (190). For the latter group, Harwood and Ebrahim compared the responsiveness of the Nottingham EADL with two other measures (191). In this study, the NEADL was not viewed as sensitive to change in function as the SF-36 or the London Handicap Scale as a measure of activity and social participation for patients with hip replacement. Despite this the scales have shown evidence of acceptable scalability, concurrent validity, and construct validity. For example, Hsueh et al. (192) used the Nottingham EADL in a study of stroke patients in Taiwan. They found that with minor modification to two items, the Nottingham EADL had satisfactory scalability and reproducibility and correlated with age and scores on the BI (192). Schlote et al. (102) studied the reliability of several scales in measuring stroke outcomes. They found that 25% of the items did not attain satisfactory reliability levels, but overall the scale showed high interrater correspondence. The NEADL scale has also been useful as a measure of the effectiveness of rehabilitation strategies, such as ADL training (193) and as an outcome measure in several studies of stroke rehabilitation (194–204) and in studies of the effectiveness of day hospitals, intermediate care facilities, and community-based care programs in facilitating independence (199,203,205).

### Frenchay Activities Index

The FAI was developed initially for use in clinical social work for stroke patients and has emerged as a frequently used measure of EADL (206). The index is designed as a mailed questionnaire to be completed by self-report. The FAI consists of 15 items divided into two sections or subscales. The first section pertains to activities performed within the 3 months preceding completion of the scale and includes standard mobility, household maintenance, and meal preparation items. The second section pertains to items performed in the 6 months before scale completion and reports on work, leisure, travel, and household/car maintenance. Items are scored on a four-point scale from 0 to 3 according to very well defined guidelines.

Turnbull et al. studied 1,280 people over 16 to construct preliminary norms and to determine evidence of reliability and validity (207). They concluded that the FAI is reliable and shows good evidence of validity with an elderly population but would benefit from adding items relating to sport, physical exercise, and caring for children. This would make it a tool more useful for a broader segment of the population (207). Green et al. studied the test-retest reliability of the FAI and other scales of stroke outcome. They found that the FAI had only moderate reliability using kappa coefficients (mean differences for items  $0.6 \pm 7.1$ ) and had higher random error

when stroke survivors were measured twice within a 1-week interval (103).

Although most of the studies using the FAI have been related to outcomes following stroke (112,208–226), the index has also been used for other populations, including those with complex disabilities (227), lower limb amputation (228,229), acquired brain injury (230), multiple sclerosis (231), and caregivers (162). The scale has also been translated for and used to study rehabilitation outcomes in Japan (232), China (233), Denmark (224), and Spain (234,235).

Carter et al. compared the postal version of the FAI with an interviewer-administered version, using a population of stroke survivors discharged from the hospital (236). Kappa statistics for individual item agreement for the subjects tested ranged from 0.35 to 1.00. Overall, the correlation between total scores was 0.94. Piercy et al. estimated the interrater reliability of the FAI as 0.93 in a study of interview administered versions of the scale by two raters (210). A study by Schuling and others suggested that the reliability of the FAI could be improved by deleting two items and by creating two subscale scores, one for domestic and the other for outdoor activities (237). Studies using the FAI and measures of BADL (particularly, the BI) have demonstrated that the scales measure different factors and may be useful in combination (233). Chen et al. found wide differences between reports by proxies and patients using the self-administered version of the FAI following stroke and against the use of this version for clinical purposes (238).

## Combined ADL/IADL Measures

### The Functional Independence Measure

The FIM evolved from a Task Force of the American Congress of Rehabilitation Medicine and the American Academy of Physical Medicine and Rehabilitation, which met to develop a reliable and valid instrument that could be used to document the severity of disability as well as the outcomes of rehabilitation treatment as part of a uniform data system (239,240).

The FIM consists of 18 items organized under six categories, including self-care (e.g., eating, grooming, bathing, upper-body dressing, lower-body dressing, and toileting); sphincter control (i.e., bowel and bladder management); mobility (e.g., transfers for toilet, tub or shower, and bed, chair, wheelchair); locomotion (e.g., walking, wheelchair, and stairs); communication, including comprehension and expression; and social cognition (e.g., social interaction, problem solving, and memory). Using the FIM, patients are assessed on each item with a seven-point scale, ranging from complete independence (value = 7) to complete dependence (total assistance required = 1 (Fig. 9-2) (241).

The original components of the FIM were developed under a federal grant to the State University of New York at Buffalo. The FIM is now part of a system of data collection and outcome under proprietary license held through association with that university. The Uniform Data System for Medical Rehabilitation (UDSMR) holds the rights to the FIM

instrument. In 1995, the Centers for Medicare and Medicaid Services (CMS) of the United States federal government (formerly known as HCFA) entered into an agreement with UDSMR to use the FIM system as the basis for the rehabilitation prospective payment system and to use the FIM instrument as part of a new client assessment instrument known as The Inpatient Rehabilitation Facility-Client Admission and Information Report (IRF-PAI). A mastery test has been developed by UDSMR to encourage consistency among users of the FIM system (242).

Granger et al. (243) studied the FIM scores for stroke patients before and after implementation of the IRF-PAI. They found evidence of differences in the ratings in four areas, which they attributed to coding changes designed to influence case mix and reimbursement. Accordingly, they urge caution in data comparisons involving years before and after implementation of IRF prospective payment guidelines.

Several studies have shown that the FIM is a reliable instrument. Ottenbacher et al. reported a meta-analysis of 11 reliability studies in 1996 (244). These 11 investigations

included a total of 1,568 patients and produced 221 reliability coefficients. The analysis demonstrated a median interrater reliability for the total FIM of 0.95 and median test-retest and equivalence reliability values of 0.95 and 0.92, respectively. The median reliability values for the six FIM subscales ranged from 0.95 for self-care to 0.78 for social cognition. For the individual FIM items, median reliability values varied from 0.90 for toilet transfer to 0.61 for comprehension. The reliability of motor subscale items was generally higher than that for items in other subscales. Additional reliability studies of the FIM have also shown similar findings.

A large number of validity studies have been reported since the inception of the FIM that have demonstrated that the scale has concurrent (245–252), predictive (253–256), and construct validity (239,248,257–261). These results have also been demonstrated with foreign (translated) versions of the scale (200,262–268). Studies have also been conducted comparing various modes of test administration, including interviews, telephone reports, and direct observations (269–271). These suggest that the FIM retains acceptable reliability under different conditions of administration.

Some limitations regarding scalability and sensitivity in the FIM have been noted. Hall et al. reported ceiling effects of the FIM at rehabilitation discharge, and particularly at 1 year after injury in a moderate to severely injured TBI population (272). Muecke et al. (256) studied the FIM as a predictor of rehabilitation outcome in lower-limb amputees. The FIM did not predict outcome of patients who were functioning lower (in bottom quartile) at admission, but it did predict rehabilitation success well in patients functioning at a higher level at admission.

To address the issue of sensitivity for use with brain injury survivors, an adjunct to the FIM, the FAM was developed by clinicians representing each of the disciplines in an inpatient rehabilitation program. Twelve items were developed in the areas of cognitive, behavioral, communication, and community functioning (273). These items are not designed to stand alone but are added to the 18 items of the FIM. The total 30-item scale combination is referred to as the FIM+FAM and requires approximately 35 minutes to administer. In 1995 a users group in the United Kingdom developed a special version of the FAM, keeping the seven-level structure, but attempting to improve the objectivity of scoring for ten items viewed as more subjective in scoring (274,275). According to Hall and Johnston, the FAM appears to add sensitivity beyond the FIM only for post-acute rehabilitation functional assessment (276,277). Although the scale items have shown acceptable reliability (230,278), a 2-year study by Gurka et al. showed that the addition of the FAM items only modestly increased the ability to predict employability and community integration in survivors of brain injury (279).

Another adaptation of the FIM, the self-reported functional measure, has been developed to quantify the ability of patients to care for themselves when they enter rehabilitation treatment and to chart their progress until they are discharged into the community or to another facility. Recent studies of

the self-reported functional measure show that the instrument predicts inpatient hospitalization but not outpatient health care use (280) and that it can also predict caregiver hours (281).

### Canadian Occupational Performance Measure

Although the Canadian Occupational Performance Measure (COPM) is not exclusively a measure of self-care, it measures self-care performance goals as identified by clients and is included as an example of a criterion measure that focuses on intervention goals viewed as important to the client (282–287). The COPM incorporates roles and role expectations from within the client's living environment using a semi-structured, individualized interview.

The COPM uses a client-centered approach to measure perception of performance over time (285,288). The therapist and client collaborate within the administration of the measure to identify goal areas, plan intervention, and provide a baseline for re-assessment. Three subsections of the interview encompass self-care, productivity, and leisure. Scores yield measures of perceived performance and satisfaction in each of the three areas. The COPM may also be used to measure specific ability limitations in order to gain an understanding of why the client may be having difficulty in a particular functional area.

The COPM measures the client's identified problem areas in daily functioning. In those instances where a client cannot identify problem areas (e.g., a young child, an individual with dementia), a caregiver may respond to the measure. The instrument takes into account client roles and role expectations and, in focusing on the client's own environments and priorities, ensures the relevance of identified areas in the assessment process. The COPM can be used to measure client outcomes with different objectives for treatment, whether those aims involve restoration of function, maintenance, or prevention of future disability. The COPM may be used across cultures (289,290), diagnostic categories (289,291–293), and age groups (146–148). Its use has even been expanded to include systems, communities, and external stakeholders (288).

The COPM is administered in a five-step process using a semistructured interview conducted by the therapist together with the client and/or caregiver. The five steps in the process include problem identification/definition, initial assessment, occupational therapy intervention, reassessment, and calculation of change scores. The original version included a procedure whereby rated importance was used as a weighting factor in calculating the performance and satisfaction scores. However, this has been eliminated based on findings from pilot studies that indicated the equivalence of scores whether or not importance weights are included.

In administration of the measure, problems are identified and defined jointly with the client and appropriate caregivers. Once the problem areas are defined, the client is asked to rate the importance of each activity on a scale of 1 to 10. The client (or caregiver) is also required to rate his or her ability to perform the specified activities and his or her satisfaction with performance on the same scale of 1 to 10. Following the initial portion of the interview, the client is asked to identify the

five top problems on a ten-point rating scale and indicate both perception of performance and perceived satisfaction. This information facilitates goal prioritization in preparation for treatment. These scores are then compared across time. There are two scores: one for performance and one for satisfaction. Administration time takes 30 to 40 minutes on average.

During initial development, the authors reported findings on an extensive pilot study of the COPM that involved administration in several countries, including New Zealand, Greece, and Great Britain (294). The scale has since been translated and used in several other countries. Early findings indicated that the average change scores for performance and satisfaction were approximately 1.5 times the standard deviation of the scores, indicating sensitivity of the instrument to perceived changes in occupational performance by clients. The COPM is viewed as a flexible instrument and appeals to clinicians who value the client-centered philosophy underlying its development (295). Some reports have indicated that patients occasionally experience difficulty with the process of self-rating of performance (296), and the suitability of the measure for use with patients demonstrating cognitive or affective difficulties has been questioned, although some studies have shown these concerns to be overstated (297). Additional concerns have been raised regarding the length of time it takes to administer the measure (288).

Reliability studies have reported intraclass correlation coefficients of  $r = 0.90$  and above for both performance and satisfaction scores (298). Trombly et al. studied the achievement of goals by adults with traumatic brain injury and found that improved scores, as measured by the COPM, accompanied client perceptions of progress on scales of independent living and social participation (299). A comparative study of rehabilitation settings for survivors of stroke using the COPM showed that participant satisfaction with goal achievement was independent of setting and consistent with the results of performance measured by IADL and health outcome scales (300). A study by Simmons et al. found that the use of the COPM, in combination with the FIM, enhances accuracy in prediction of outcomes for rehabilitative services for persons in adult physical disabilities settings (146). More recently, the reliability and validity of the COPM with parents and pediatric populations has been studied (147,148). Cusick et al. (147) studied the internal reliability and validity of an adapted version of the COPM with young children. The study concluded the adapted version was psychometrically robust and appropriate to pediatric populations.

Additional recent studies continue to demonstrate positive results in the psychometric properties of the COPM (289,290, 293,301,302). Dedding et al. (302) studied the convergent and divergent validity of the COPM in two Amsterdam hospitals. The study demonstrated evidence of the instrument's validity and the authors concluded the unique nature of the COPM in affording clients the opportunity to self-rate any self-care, productivity, or leisure activity. These and several other studies have demonstrated that the COPM correlates well with other measures of ADL outcome, motivates active

participation and adherence to rehabilitation regimens, and improves satisfaction with services for a variety of diagnostic groups and ages (61,301,303–307). The COPM appears to provide useful information regarding self-care performance from the standpoint of the recipient of care.

### Self-care Evaluation of Children

Information presented to this point has been based on self-care and ADL assessment as it pertains to adults. It is worth noting, however, that self-care assessment of the pediatric client requires a number of special considerations. These pertain to incorporating developmental milestones into the structure of the assessment, interacting with the child during the assessment process, and when appropriate, obtaining a parental view of the child's performance.

Within pediatric self-care assessment, practitioners consider the child's physical, cognitive, psychological, and social emotional skills along with the environmental impact on daily function. Personal, social, and parental factors influence a child's self-care performance. A child brought up in a home where value is placed on grooming, may develop those skills in advance of a child whose home environment places emphasis on academics or sport. Consideration of the interaction of the child, environment, and self-care activity is integral; holistic evaluation should include both direct evaluation of the child and assessment of the environmental supports, and barriers to occupational performance. Two widely used instruments that have attained sufficient use to establish their value in the clinical setting as useful measures of functional performance in children are the *WeeFIM* and the *Pediatric Evaluation of Disability Inventory*.

### FIM for Children (WeeFIM)

In 1987, the FIM was adapted to meet the need for a reliable and valid functional assessment tool that would be useful in measuring the severity of disability in children. The resulting Functional Independence Measure for Children (WeeFIM) (308) was designed to measure the functional ability in a developmental context. In 2005, the WeeFIM II System Clinical Guide was developed and added a 0 to 3 module in addition to an Internet-based software program to the existing WeeFIM system (309). The WeeFIM II is designed for children ages 3 to 7 (or those falling below a developmental age of seven) and includes a minimal data set of 18 items that measure performance in the areas of self-care, mobility, and cognition. The scale uses the same seven-point ordinal scale to assess level of function (graded from dependence to independence) as the parent tool, the FIM. The WeeFIM 0 to 3 module is designed for children ages 0 to 3 and measures developmental performance in motor, cognitive, and behavioral performance utilizing a three-level rating system (3-usually, 2-sometimes, 1-never). The 0 to 3 module is designed to measure early functional performance and serve as a measurement for functional outcomes over time.

In conjunction with the development of the WeeFIM II, clinicians may now subscribe to the WeeFIM II system

through the UDSMR. Subscription to the system includes specific modules including inpatient and outpatient modules and the 0 to 3 assessment tool. In addition, subscribers also receive quarterly benchmark reports, clinical and technical support, software for reporting and submitting online data, and a variety of other services to facilitate use of the FIM. The software system may also be used to interface with data reporting for the Joint Commission on Accreditation of Health Care Organizations.

Although continued research is needed on the WeeFIM II and the use of the 0 to 3 module, there is sufficient data to warrant the use of the WeeFIM in a variety of pediatric populations. Studies of the WeeFIM have shown a strong correlation between the scale scores and age, with the subscale scores involving gross and fine motor skill demonstrating the highest correlations (310). Data showed that tasks on the WeeFIM demonstrate a developmental sequence, with an observed positive relationship between the complexity of tasks and the age at which children achieve independence in their performance (311). Repeated evaluations of the scale and comparisons of personal and telephone interview ratings have demonstrated that the scale has good stability and equivalence reliability (312). In different studies and under varying conditions, the intraclass correlation coefficients for the six subscales have ranged from 0.73 to 0.99, and test-retest reliability has been estimated at 0.98 for children with disabilities and 0.99 for able-bodied children (312). Total score intraclass correlation coefficient values have consistently been greater than 0.95 (236). Comparisons of personal assessment and telephone interview ratings have found the scale to be consistent for items, subscales, and total test scores under those varying conditions of administration (312).

Comparisons of WeeFIM scores with other developmental tests, including the Vineland Adaptive Behaviors Scales and the Battelle Developmental Inventory Screening Test, found subscale correlations of 0.42 to 0.92 and total score correlations of 0.72 to 0.94 (313). Additional research comparing the WeeFIM to two standardized language tests, the Symbolic Play Test and the Reynell Language Development Scale, demonstrated high correlations in a Hong Kong pediatric population, the authors concluded from their pilot study that the WeeFIM appears to be an easy to use functional assessment of language in children with developmental delays (314). Comparisons of the WeeFIM with the Pediatric Quality of Life Inventory appear to be fair to moderately correlated in areas of physical health, but significant differences were not found in areas of psychosocial function, suggesting the tools may measure different constructs within the psychosocial area (315).

Several studies have been conducted on the validity of the WeeFIM and have used the instrument to measure the developmental and functional status of children with and without disability and across cultures (316–318). The scale has also been used to assess the functional status and rehabilitative progress in those with genetic impairments (240), heart defects (241), cerebral palsy (319–322), spina bifida

(323), Down's syndrome (324), and Rett syndrome (325). It is also useful in documenting progress and development following extreme preterm (246) and very-low-birth-weight delivery (247,248), primary brain tumors (249), and dorsal rhizotomy (250), in addition to rehabilitation following traumatic brain injury (251,252,326) and pediatric spinal injury (253). The WeeFIM has also been used to measure rehabilitation outcomes in larger populations across diagnostic, age, and rehabilitation cohorts (327). In summary, the WeeFIM is a useful instrument for measuring self-care performance in children. Additional research is warranted to continue to validate psychometric properties in the newer version, including the 0 to 3 module and the WeeFIM's application to other cultures.

### Pediatric Evaluation of Development Inventory

The Pediatric Evaluation of Development Inventory (PEDI) is described as a comprehensive assessment that samples key functional capabilities and performance in children from the ages of 6 months to 7.5 years. The scale may also be used for older children if their functional abilities fall below that expected of 7.5 year old children without disabilities (328). The scale is designed to be used with children having a variety of disabling conditions and can be administered by professionals or by structured interview, or parental report. The PEDI addresses both capability and performance in the areas of self-care, mobility, and social function. These three domains are further divided into subunits that comprise each task. Capability is determined by identifying the functional skills for which a child has demonstrated mastery, with scores reflected on the Functional Skills Scales. Two other subscales are provided. One is the Caregiver Assistance Scale, which measures the extent of help provided to the child during typical daily situations, and the other is the Modifications Scale, a measure of environmental modifications and equipment used routinely in daily activities. The PEDI has 197 functional skill items and 20 items that measure caregiver assistance and environmental modifications. The PEDI was designed to determine functional capabilities and deficits, to monitor progress, and to evaluate therapeutic outcomes. Table 9-8 lists item domains and complex activities included in the PEDI.

During the development of the PEDI, content validity was determined through use of a multidisciplinary panel of experienced experts (329). Items were derived from a wide array of functional performance and development scales. Normative data were collected from 412 children and families from the northeastern United States with a sample stratified to represent national population demographics while retaining equal representation across the target age groups using 6-month intervals. A detailed manual with scale development data, administration instructions, and scoring has been developed. The scale also has published scoring forms and software.

Six domain scores are provided that enable a profile of relative strengths and weaknesses in both functional skills and

**TABLE 9.8** Content of the Pediatric Evaluation of Disability Inventory

	Self-Care Domain	Mobility Domain	Social Function Domain
Function skills scale	Types of food textures	Toilet transfers	Comprehension of word meanings
	Use of utensils	Chair/wheelchair transfers	Comprehension of sentence complexity
	Use of drinking containers	Car transfers	Functional use of expressive communication
	Toothbrushing	Bed mobility/transfers	Complexity of expressive communication
	Hair brushing	Tub transfers	Problem resolution
	Nose care	Method of indoor locomotion	Social interactive play
	Handwashing	Distance/speed indoors	Peer interactions
	Washing body and face	Pulls/carries objects	Self-information
	Pullover/front-opening garments	Method of outdoor locomotion	Time orientation
	Fasteners	Distance/speed outdoors	Household chores
	Pants	Outdoor surfaces	Self-protection
	Shoes/socks	Upstairs	Community function
	Toileting tasks	Downstairs	
	Management of bladder		
	Management of bowel		
Complex activities assessed with caregiver assistance and modifications scale	Eating	Chair/toilet transfers	Functional comprehension
	Grooming	Car transfers	Functional expression
	Bathing	Bed mobility/transfers	Joint problem solving
	Dressing upper body	Tub transfers	Peer play
	Dressing lower body	Indoor locomotion	Safety
	Toileting	Outdoor locomotion	
	Bladder management	Stairs	
	Bowel management		

caregiver assistance across the domains tested. No composite summary score is provided; with the rationale that this would obscure meaningful differences in functional performance within specific domains. Scaled scores can be computed to provide an indication of where a child's performance falls relative to the possible maximum. Item difficulty for the PEDI was determined through Rasch analysis, which was also used to estimate goodness of fit between individual subject profiles and the overall hierarchy, intended for each subscale. Since each scale is self-contained, it can be used individually or in combination with other scales. The average time for administration is 45 to 60 minutes.

The psychometric properties of the scale are reported in the administration manual (328). Reliability data (internal consistency) for the six scale scores were computed using Chronbach's alpha, with coefficients ranging from 0.95 to 0.99. Using the clinical samples, ICC values for inter-interviewer reliability for the scales was estimated at 0.84 to 1.00. Values for independent respondents ranged from 0.74 to 0.96. Selected modifications in the PEDI were made based on these data. Initial scale data reflected an expected progression of functional skills according to age. Initial concurrent validity was established through comparison of scores on the PEDI with scores on the Battelle Developmental Inventory Screening Test and the WeeFIM. These correlations were generally high for self-care and mobility but lower for social

function. In early studies of the scale's ability to detect change, results were mixed, with one clinical sample of children with mild to moderate traumatic injuries demonstrating positive changes on the PEDI in all domains. Another clinical sample involving children with multiple significant disabilities showed positive change after 8 months only on the mobility scale. Some scores for this group decreased, indicating that the children were falling behind their peers in age-expected functional levels (328). Ludlow and Haley studied the influence of setting (context) on rating of mobility activities and found that parents in the home setting tend to use stricter criteria in their ratings than rehabilitation professionals in the school setting, although both can be trained to attain a satisfactory level of consistency (330).

Since its initial development and normative studies, several clinical studies using the PEDI have been reported. These have related to measuring the status of very-low-birth-weight children at age 5 and for various rehabilitation or surgical interventions with children in various diagnostic categories, including traumatic brain injury (331–334), spinal bifida (335), cerebral palsy (336–338), and osteogenesis imperfecta (339,340). In addition, several reports have been published where the PEDI has been used to measure outcomes following targeted medical and surgical interventions for cerebral palsy (341,342), including studies of posterior rhizotomy (343–345), the use of botulinum-A toxin injections (346,347),

and surgical release (348). Ketelaar et al. studied the properties of 17 scales assessing the functional motor abilities of children with cerebral palsy and concluded that the PEDI was one of only two measures that demonstrated acceptable psychometric properties while having the capability to document changes in function over time (349).

Studies of children from outside the United States have been reported to ascertain the suitability of using the PEDI with other cultural groups. Custers et al. compared profiles of non-disabled Dutch children with normative profiles and found enough differences to recommend the cross-cultural validation of the PEDI before use in the Netherlands (350). More recently, the reliability of the Dutch version was found to have positive psychometric properties, with the inter-interview reliability exceeding that of test-retest and inter-respondent reliability (351). The authors concluded that the psychometric properties of the Dutch version were “good” but that minor adaptations needed to be made (351). Similar recommendations were made after a study of children in Puerto Rico (352). These studies led to recommended item modifications for use in those countries (353). A study of the applicability of the PEDI in Slovenia found statistically significant differences in functional skills and caregiver assistance scores between Slovene children and the American normative group (354). The authors concluded that the American normative data are not fully appropriate for reference with the Slovene population (354). In Norway, a study of the applicability of the PEDI utilized a previous translation of the PEDI utilizing international guidelines (355) and found the Norwegian

sample scored significantly lower for functional skills in mobility tasks than the American children. Other areas were similar between the two groups yet the authors recommended further research from which Norwegian reference values can be derived (355). In summary, the PEDI has wide range applicability across diagnostic groups. Although it is widely used internationally, further research is needed to explore its reliability and validity in various cultures. (Readers should note that the PEDI is now under revision and should consult the developers for latest version.)

## MANAGEMENT OF BASIC SELF-CARE SKILLS

The functional evaluation process characterizes the strengths and weaknesses of each client in relation to specific daily living skills. The practitioner or rehabilitation team uses this information to develop options for a plan of care that will assist or enable the client to become more independent in selected activities. Figure 9-3 provides a hypothetical therapy plan of care for a client with right hemisphere stroke. Research has shown that patients who collaborate in identifying goals and selecting treatment options become active and responsible participants in their own rehabilitation. Most intervention approaches fall into one of four categories: remediation, compensation, disability prevention, or health promotion (356). These categories are consistent with what people do when they cope with functional limitations without professional advice.

**FIGURE 9-3.** Self-care goals and intervention strategies.

Evaluation Data	Problem List	ADL Goals	Intervention Strategies
<b>HISTORY/NARRATIVE</b> Client is male, 67 y.o., retired school administrator. Active pre-morbidly in volunteer work and outdoor hobbies.	<b>MEDICAL DIAGNOSES</b>  Right CVA Depression	Client will demonstrate improved upper extremity endurance and strength so that with task modifications and assistive devices, he is able to dress independently in less than 30 minutes.	<b>REMEDIATION</b> Techniques to encourage use of affected extremity Improve strength, coordination
<b>SENSORIMOTOR</b> Proprioception intact Grade 3(Fair) muscle strength in Left wrist, elbow, and shoulder flexors and extensors No visual field cut 2 point discrimination absent on R digits	<b>PERFORMANCE LIMITATIONS</b>  Unable to initiate or complete dressing or bathing tasks without verbal cues and physical assistance.	Client will shower independently using adaptive equipment and safe practices.	<b>COMPENSATION</b> Train in use of dressing skills Introduce dressing aids (stocking aid, zipper pull, velcro closures) Train family members
<b>COGNITIVE</b> Follows simple directions	<b>FUNCTIONAL LIMITATIONS</b>		
<b>AFFECTIVE</b> No interest in activities	Left Hemiparesis Apathy		<b>DISABILITY PREVENTION</b> Grab bars in tub/shower Non-slip surfaces

## AN OVERVIEW OF INTERVENTION APPROACHES

The major categories of ADL intervention described earlier are briefly described in the following sections. Determination of the most appropriate treatment approach is, ideally, collaboration among the client, caregiver, and health-care team. The therapeutic approach that is the best match intervention considers the clients' needs, desires, and expectations as well as capacity for learning, the prognosis for the impairments, the time available for intervention, and the anticipated discharge environment.

### Remediation

Remediation is the re-acquisition of functional or structural deficits, or the acquisition of new skills in the area of skilled movement, cognition, or social function. In this approach, one expects that lost skill or ability will be regained. Rehabilitation approaches are used to establish or reestablish the client's skills, habits, and routines. Consequently, the use of this approach implies an active learning process whereby patients must adapt to functional and environmental limitations as they affect the demands of everyday life. The initial acquisition of skills by those who are developmentally or congenitally disabled at birth is a markedly different learning process from the reacquisition of daily living skills by those who have been independent at such tasks before becoming disabled. When the goals of remediation are to develop skills in a person with a congenital condition, the training process is described as *habilitative*. When the goal is to achieve previous functional levels for a person with an acquired disability, the training process is described as *restorative*.

The best candidates for remediation or restoration of skills often involve a client who may make considerable contributions to the therapy process based on his or her previous knowledge and understanding of how the task was performed. Such patients can monitor their own errors and often use appropriate strategies to minimize deficits. In this case the treatment session is used to develop a practice strategy and the client practices self-care at each opportunity whether or not the therapist is present. Problems occurring between treatments are discussed, and possible solutions can be practiced during the next treatment session. Implied in the process of remediation is the ability to learn. Learning strategies and implementing teaching strategies to optimize learning are important in this process.

### Learning Strategies

The first key to establishing a positive learning environment for a client is to ensure that the set goals are relevant and meaningful to the client. Meaning refers to the sense that is made or the personal implications that are drawn from, engaging in self-care tasks. Nelson et al. (357) define meaning as an interpretive process in which increasing the purpose

of a task can improve the meaningfulness of a given activity. For example, embedding an exercise within an activity of daily living (or occupation) added purpose to the exercise and thereby increased the likelihood of accomplishment of the task. Involving the client and family in the goal-setting stage can help engineer a match between learning and capabilities by improving meaning and therefore motivation to accomplish the task.

As research has unveiled the importance of specific learning strategies in both acquisition and re-acquisition of functional skills, rehabilitation professionals have incorporated these strategies into training. There are a variety of classification schemes for describing these learning strategies. In practice, four stages of learning described by Bertoti are helpful in differentiating between the initial stages of learning (e.g., acquisition) and the long-term stages of learning that may include maintenance, fluency or proficiency, and generalization. This incremental learning process, moving from initial instruction to mastery with graded assistance, is sometimes termed *scaffolding* (358).

Optimal learning in the initial stages requires different strategies from those for retention or long-term learning, but most of the teaching strategies are used at both the initial and long-term learning strategies, albeit in different ways. Some of those strategies for learning are highlighted in Table 9-9. Research also indicates that learning is enhanced when the learner engages in a naturally occurring task versus use of progressive resistive exercise and by using real objects in a natural context (357,359–363).

The strategies employed by the therapist in each stage includes anticipation of the needed instruction, application of physical or verbal guidance, timing of extrinsic feedback, emphasis of intrinsic feedback, and the orchestration of practice (358,364).

### Instruction

Instruction prior to initiation of any task is crucial for motivation and for clarification about the task and can take the forms of verbal, demonstration, and modeling. Verbal instructions help to focus the client's attention on important aspects of the task. The therapist may choose to break down verbal instruction into one or two essential elements. Verbal instructions that are both brief and clear are the most helpful to clients. In addition, a therapist may use demonstration or modeling of the task to either replace or enhance the verbal instructions. Demonstrating how the client is to achieve the task has clearly been demonstrated to promote learning. Effective teaching strategies require a thorough task analysis to identify barriers to learning and to determine prior knowledge and current capabilities of the learner. In addition, effective training includes the use of active learning strategies, engagement in motivational and collaborative activities, adaptation to the learners' abilities, and use of real objects (362,363). The teaching and implementation processes are highlighted in Table 9-10.

**TABLE 9.9 Strategies Used During Different Stages of Learning**

Strategy	Acquisition Stage	Long-term Learning
Extrinsic Feedback	Use of multiple types of cues (verbal, tactile, videography, and biofeedback), given both frequently and concurrently with the task performance	Decreased quantity of the volume of feedback, give information less frequently, and fade the amount of feedback given Offer summary feedback after task completion Provide feedback about the knowledge of results Provide variation and interference with performance to promote generalization
Practice	Encourage both physical and mental/imagery practice Provide opportunities for the task repetition Consistency Use part practice to master components Blocked practice Correct only significant errors Give opportunities to fixate on closed skills Require cognitive activity and problem solving	Promote production of the entire movement pattern Encourage problem solving, searching for active solutions Practice within context of task Provide random and serial or variable practice Differentiate movement Ensure diversification of skills
Guidance	Manual contact in conjunction with verbal cues Trial and error may promote frustration so limit the variation of practice to promote a balance toward success of task completion	Avoid manual cues Don't over cue Allow for trial and error

### Guidance

Guidance, also referred to as facilitation, assists the client with execution of an action. Guidance has been shown to be effective in the acquisition phase of learning novel tasks, particularly when it is graded and is then extinguished to match the client's skill development (358). The implementation of guidance is most effectively used when the following circumstances exist: when the client is in the initial learning stage, is performing tasks that are naturally completed at a slower rate, or is unfamiliar with the task. It is also used for prevention of injury

or reduction of fearfulness during movement. The overall goal is to reduce the use of guidance while promoting independent practice.

### Feedback

Feedback is critical to the rehabilitation process and can greatly enhance the success in performing ADLs most efficiently. However, care must be taken to select the appropriate type and quantity of feedback based on the needs of the client. There are several types of feedback that incorporate both intrinsic (i.e., internal sensory cues) and extrinsic (e.g., verbal, tactile, knowledge of results) information. These are highlighted in Table 9-11.

**TABLE 9.10 General Procedures for Implementing Teaching and Learning Strategies during Skill acquisition**

Identify and address barriers to learning the activity or occupation.  
Determine the learner's prerequisite skill set and learning needs.  
Engage the client and caregivers in joint goal setting then employ active learning strategies, observation, and demonstration.  
Provide a nurturing, safe, and supportive environment.  
Provide activities that pose an adequate challenge to the client, using grading and adaptation to create this appropriate challenge.  
Provide opportunities for practice in context, using the appropriate practice schedule for skill level.  
Facilitate use of feedback (both internal and external) and physical guidance during skill acquisition.  
Transfer learning by engaging client in active problem solving, use errors as a positive learning opportunity.

## Practice

Practice is an important aspect of all motor training. Mere repetition of activity is not therapeutic training. The therapist or other self-care trainer must provide task structuring, strategic prompts, and suggestions for improvement of performance. The client or learner must learn to monitor and correct performance errors. Over time, desirable behaviors must be systematically rewarded and undesirable behaviors ignored or extinguished.

Practice usually occurs only at the time or times each day that a task is appropriate. During the initial or acquisition stages of instruction, therapists can promote generalization and mastery by teaching under natural conditions, using real equipment rather than simulated tools, involving multiple teaching conditions (locations, instructors, materials), and selecting the instructional examples carefully, with attention to those that best sample the range of variation likely to be encountered in task performance. Learners are encouraged to do what they can to help—sometimes starting a task that the therapist will need to finish and sometimes completing a task that only the therapist can initiate.

For the client with an acquired disability, relearning self-care independence is a distinctly different process than for the habilitation client. First, there is a loss of self-esteem and sense of failure and frustration when one is unable to perform those tasks that often are taken for granted by non-disabled persons. Initial learning usually is motivated by intrinsic rewards of increased competency at self-care tasks and by the positive social reinforcement of parents and other caregivers. In learning a task, negative reinforcement (i.e., avoiding unpleasant experiences or consequences) such as avoiding embarrassment over having to ask for assistance for feeding or toileting may be far more effective than positive social reinforcement. The therapist who tries to use social praise to reinforce practice of toileting skills will find that it is not effective. In fact, it probably will be viewed as demeaning to praise an adult in a situation reminiscent of a childhood experience.

Although many physically disabled adults with acquired deficits may not fit the above description, those who also have significant cognitive or perceptual deficits may not be appropriate. Conditions such as apraxia may significantly influence the effects of self-care training and may need to be remediated before ADL training. Recent studies, while inconclusive, suggest that such concurrent treatment may be useful (365). For such clients and those for whom other approaches have failed to produce results, compensatory training and modification should be considered.

Other remediation strategies focus on the restoration of biological, physiologic, or neurologic processes. For example, the practitioner may incorporate motor or sensory techniques to fully or partially develop or restore sufficient voluntary control or movement to enable task accomplishment. Techniques derived from theories of neuroscience, biomechanics, and motor control are included among remediative approaches. The objective is to recover sufficient perception, cognition, and voluntary movement to enable task performance in a safe

and effective manner. It is noted, however, that studies have shown that body structure and function predict less than half of the variation in task performance. In particular, the literature on stroke rehabilitation shows that gains in organ/physiologic (impairment) skills are small and do not automatically result in improved functional performance. Trombly analyzed the results of several studies in which correlations between motor impairment and ADL were reported. Her findings indicate that the amount of variance in ADL accounted for by motor impairment was 31%. Most (approximately 69%) of the variance associated with ADL performance was derived from other factors unrelated to the physical impairment. Motivational and environmental factors explain most task performance variations (359–361).

In the restorative approach, training is frequently combined with compensatory strategies, such as the use of ATDs, prostheses, or orthoses. For example, the individual with only one functional arm can continue to be independent in dressing by learning to select certain clothing and/or by substituting motions and using devices for dressing. When remediative approaches are inadequate or are too costly in terms of time, energy, or expense, compensatory or adaptive approaches are necessary.

When able-bodied children learn self-care tasks initially, they do so over extended periods of time. Anthropologists note that there is a regular sequence of self-care independence that is supported by child development studies across cultures. Feeding, grooming, continence, transfers, undressing, dressing, and bathing usually occur in this order, with normal acquisition influenced by the appearance of readiness skills.

Even such limited information as this may be useful in habilitation training. Using a distributed practice schedule (i.e., teaching self-care activities only during those times they would normally be performed) is critical for the person unfamiliar with the concept of the task. Effectiveness in self-care training involves learning the appropriate times and natural sequences of daily activities. The client who is relearning a task often retains an appreciation of when it is to be performed, but the client being habilitated needs to learn not only the skills but also the context appropriate to each task. Thus, in habilitation training, the acquisition of self-care skills may occur over extended periods and involves the careful structuring of tasks, frequent monitoring to correct performance errors, and feedback.

## MAJOR SELF-CARE CONSIDERATIONS BY FUNCTIONAL LIMITATION

This section concerns special problems and issues related to ADL performance limitations associated with specific functional deficits. Perhaps the most important concept in rehabilitation aimed at daily living skills is that neither the type nor the severity of the disability can be used exclusively to predict how independent a given client will be. For example, Putzke et al. determined the predictors of ADL function

among cardiac transplant candidates and found no correlation between certain expected physical variables and IADL capacity (366). Limited capacity for exertion, which is used by many occupational and physical therapists to recommend appropriate activities, was not a determinant of the activities those cardiac clients performed as part of their daily routine. The researchers concluded that client perceptions and not cardiac symptoms accounted for the patterns of independence/dependence in household and social activities. A study of self-care and aging by Norburn et al. (367) identified three types of self-care coping strategies. These were related to the use of equipment or devices, specific changes in behavior, and modifications of the environment. The study also found that receiving assistance sometimes was used to supplement self-care coping strategies.

Is it useful, then, to discuss self-care considerations by functional limitations? If the goal is to become aware of special problems or issues unique to a particular disability and not to predict outcomes, then the answer clearly is affirmative.

Some studies of physical function have provided useful theoretical associations between diseases and reports of difficulty with clusters of tasks within IADL routines. In a useful statistical analysis, Fried et al. studied 5,201 men and women age 65 and older in four U.S. communities (368). They analyzed difficulties associated with 17 tasks of daily

life and found four clusters of activities where difficulty with one task was associated with reported difficulty with other tasks in that group. The groups included activities primarily dependent on mobility and exercise tolerance, complex activities heavily dependent on cognition and sensory input, selected basic self-care activities, and upper-extremity activities. These groups were then examined to see if they were associated with underlying impairments based on regression analysis using 15 chronic diseases and conditions. They found that physiologic and disease characteristics significantly correlated with difficulty in each of these four groups. The implications of this study pertain to the appropriateness of outcome measures, which the authors suggest should be chosen with defined physiologic rationale. However, the study also provides a general indication of patterns of ADL/IADL consequences associated with the 15 conditions (verbal, tactile, knowledge of results). These are highlighted in Table 9-12.

Several useful conclusions related to the performance of life tasks can be gleaned from this study. First, it is evident that problems with body structure and function seldom affect isolated tasks or task categories. Thus, some health functional difficulties influence performance across all task categories. These could include depression, joint pain and stiffness, visual impairments, shortness of breath, and both generalized

**TABLE 9.12 ADL/IADL Task Groups Found to Be Statistically Associated with Underlying Medical Conditions<sup>a</sup>**

Group	Mobility	Complex (Cognitive/Sensory)	Self-care	Upper Extremity
Tasks	Walk 1/2 mile Climb ten steps Transfer from bed to chair Walk in own home Heavy housework Lifting or carrying ten pounds of groceries	Pay bills Meal preparation Shopping Light housework Telephone use	Using toilet Dressing Bathing Eating	Gripping Reaching

Disease association (difficulty with one or more tasks in group)	Congestive heart failure Cancer Arthritis Stroke Diabetes Emphysema Hypertension	Arthritis Stroke Diabetes Emphysema Hypertension	Myocardial infarction Arthritis Stroke Diabetes Emphysema Hypertension	Arthritis Stroke Diabetes Emphysema Hypertension

<sup>a</sup>Fried LP, et al. Physical disability in older adults: a physiological approach. *J Clin Epidemiol.* 1994;47(7):747–760.

and hand grip weakness. Although these associations can help practitioners to anticipate certain activity and participation limitations associated with given diseases and their accompanying functional pathology, each case must be considered in the context of a particular client's circumstances.

From the standpoint of rehabilitation intervention, these data suggest that some generalized strategies for improving endurance and strength can have the potential for broadly benefiting ADL/IADL performance on several tasks. In those cases where the underlying etiology of task difficulty cannot be addressed, such as with weakness and shortness of breath accompanying congestive heart disease, general compensatory strategies to address performance of self-care and IADL tasks will be necessary.

The following sections summarize recent studies related to interventions and outcomes for selected areas of task-related functional pathology. Practitioners are encouraged to consult the many intervention textbooks now available in the rehabilitation sciences for theoretical and applied (procedural) guidelines and details associated with implementing intervention strategies (369–371). Although many interventions have not yet been subjected to controlled study, it is important for practitioners to be aware of the literature in order to determine the available evidence underlying a particular intervention technique.

### Cognitive and Perceptual Deficits

Diminished cognitive and perceptual function can be a consequence of senile dementia, traumatic brain injury, stroke, or developmental disability. The ability to attend; perceive and select relevant information in the environment; make logical decisions; plan and execute safe, goal-directed action; and remember events involves aspects of executive function, which may be compromised in cognitive dysfunction. Individuals with cognitive and/or perceptual loss must be approached and managed with greater care and attention than other clients.

The association between cognition (particularly executive function) (372) and ADL/IADL performance is well documented. Studies of community-dwelling seniors (373–375), persons following hip fractures (134,376,377), clients with cerebral palsy (378), and stroke clients (379–381) are among those documenting this association. However, Perneczky et al. argue that the presence of cognitive impairment affecting complex ADL should not be used as a criterion for diagnosing dementia (382).

Sometimes cognitive loss is associated with agitation, particularly following traumatic brain injury or in senile dementia. For example, Bogner et al. found that the presence of agitation predicted longer length of stay and decreased functional independence following traumatic brain injury (383).

In stroke, generalized cognitive deficits are most common in clients with frontal lobe insults. Cognitive deficits involving visuospatial abilities are associated with right hemisphere strokes and apraxia. Disorders of learned movement or motor planning are found with left hemisphere strokes. Unilateral neglect, or inattention to the side opposite the affected

hemisphere, is also a difficult consequence of stroke and can occur in up to half of clients with right brain damage and less frequently in left hemisphere strokes. Unawareness of the stroke or its results can be found in clients with strokes in the non-dominant hemisphere. This appears to be related to the location and severity of brain damage, or the extent of cognitive impairment (384–386). Typically, these deficits interfere with regaining skills in ADLs. Clients with spatial constructional problems often have difficulty in eating, dressing, grooming, and walking. Those with unilateral neglect experience difficulty with reading, writing and numerical tasks, as well as in using a phone or driving.

Several studies have found that perceptual motor abilities are significant predictors of self-care and ADL in clients with CVA (387–390). In a systematic review, Rubio and Vandeusen summarized the research on perceptual deficits and ADL-targeted intervention approaches following stroke (391). They acknowledged the convincing evidence, associating perceptual difficulties with poorer ADL outcomes and noted that little attention has been paid to agnosia and that controlled studies comparing various intervention options are needed.

The literature documents many attempts to use perceptual training in addition to task-oriented (functional) training as a way of improving ADL outcomes in clients with perceptual problems, such as unilateral neglect following CVA (392). Strategies for perceptual remediation include (a) visual scanning training with verbal cuing for visual anchoring, (b) increased client awareness of neglect to encourage use of compensatory mechanisms, (c) increased sensory stimulation to the affected side, and (d) activation of the affected extremity on the affected side of the body. Overall, although it has been shown that interventions targeted for perceptual skills can have short-term effects in improving perceptual skills (393), research has not demonstrated unequivocally that perceptual training in addition to traditional functional intervention improves outcomes in ADL over functional training alone. Clients with such limitations can and do make progress, albeit more slowly than similar clients without such deficits. At least one study has shown that training that includes specific compensation strategies along with traditional ADL strategies can improve overall performance in ADL skills for CVA clients with left hemisphere stroke (394). Unfortunately, there is a dearth of information on the long-term results of perceptual interventions.

Treatments for apraxia or motor planning, and execution deficits have included such strategies as manual guided movement, the use of objects and situations that elicit automatic motor responses, and systematic stepwise training (“backward chaining”). Controlled studies of the long-term efficacy of these approaches for improving functional ADL skills have not been reported.

### Depression

Numerous rehabilitation studies have shown that the presence of depression following stroke and other health events (such as hip fracture, post-polio syndrome, traumatic brain injury) can

predict poorer functional outcomes and diminished well-being (395). Families and caregivers can be an important source of monitoring for depression, and mild depression often resolves or can be managed through behavioral interventions such as encouragement, attention, or active participation in suitable activities. More severe depression should be confirmed by accurate diagnosis. Symptoms may be effectively managed through medication (396). However, it appears for clients with CVA that the reduction in symptoms, particularly if started early, can result in improved levels of ADL function at discharge (397) but its presence reduces the proportion of excellent outcomes. A controlled study by Desrosiers et al. showed that a leisure education program could reduce depression and increase participation in leisure activities by stroke survivors (398).

Craig et al. reported on a program of cognitive behavior therapy designed to reduce depression and improve self-esteem during rehabilitation following spinal cord injury. Their study improved anxiety, mood, and self-esteem of those receiving the intervention but did not result in outcomes that were significantly different from those of clients receiving traditional rehabilitation. Interestingly, studies of suicide following spinal cord injury show that frequencies are higher among those with marginal functional disability than in those with complete lesions.

### Upper-Extremity Impairment

Upper-extremity impairment can be bilateral, as in spinal cord injury and arthritis, or unilateral, as may be the case following stroke, traumatic injury, amputation, peripheral nerve injury, or complex regional pain syndrome (CPRS/reflex sympathetic dystrophy). Bilateral upper-extremity amputation, loss of motion due to hemiparesis of nerve injury, and weakness are serious threats to self-care independence and may be helped with prosthetic and orthotic devices. Unilateral upper-extremity impairment most often is compensated for by use of the uninvolved extremity. When disability affects the preferred hand, there will be a need to transfer the skill to the other hand. This may or may not require coordination and dexterity training.

Persons with unilateral upper-extremity amputations will often be able to accomplish most of their ADL with one arm. Thus, it is important to fit the unilateral upper-extremity amputation with prosthesis within 3 months of losing the arm in order to facilitate training for bilateral patterns of use. The prosthesis always functions as the nonpreferred extremity in stabilizing objects (398).

Cosmesis may be a key factor for the client in the selection of a prosthesis, which can be body powered, myoelectric, or hybrid. Bilateral upper-extremity amputations, particularly if above the elbow, are more challenging but can result in successful independence. The prosthetic training for a bilateral above-elbow amputee usually requires a carefully designed series of training sessions. Initial training of BADL requires an extensive time, effort, and motivation on the part of the amputee. Often the basic tasks of writing, eating, brushing

teeth, washing the face, and requiring assistance with dressing are the most realistic goals during rehabilitation following the prosthetic fitting. Later training can concentrate on additional activities in the daily routine (398).

### Lower-Extremity Impairment

Mobility and transfer limitations are the most significant self-care problems for lower-extremity impairments, including those with hip fractures, amputations, arthritis, and paraplegia. Often wheelchairs or other ambulation aids are needed for independent mobility. Bathroom safety equipment, dressing aids such as extended handle shoehorns, and raised seats often are useful items that may be used either temporarily or permanently. Rearrangement of living space to permit wheelchair access or access using other mobility aids often is necessary. Ramps, chairlifts, and additional railings may be needed if stairs are present. For the person using a wheelchair, it also may be helpful to consider rearrangement of shelves, drawers, and closet space to permit frequently used items to be reached from the wheelchair. Studies have shown an association between the need for mobility devices following lower limb amputation and reduced ADL independence (229,399,400).

### Upper- and Lower-Extremity Impairment

Persons with tetraparesis or tetraplegia from traumatic spinal cord injury, cerebral palsy, muscular dystrophy, multiple sclerosis, or amyotrophic lateral sclerosis must rely on a wide range of options for self-care independence. In most cases, there will be a need for attendant care, assistive devices, and modifications of living space. Such people often require high-technology devices, such as environmental controls, augmentative communications, and other microprocessor-based systems to be fully independent in their own homes (401). Promising developments are being shown in the technology associated with implanted neuroprostheses for restoring hand grasp and enabling ADL performance in tetraplegia following spinal cord injury (402,403).

### Pain

The disabling consequences of low back pain or CRPS/reflex sympathetic dystrophy frequently include intractable pain, sensory changes, edema, and movement disorder, which can include restricted or involuntary movement and atrophy of the upper or lower extremity. Pain syndromes (404–407) can result in marked functional limitations affecting ADL performance, usually caused by pain rather than by restricted motion (408). Treatment often consists of medications or TENS to assist with pain control and compensatory training for alternative methods in accomplishing daily living tasks (408). In a recent systematic review, it was concluded that information based on a biopsychosocial model is a more efficient strategy to modify clients' beliefs on pain and consequences, and increase the adherence to exercises. Thus, it seems necessary to focus as much attention on a client's beliefs about chronic pain and gaining participation in regular exercise practice to prevent pain pathology (409).

### Loss of Use of One Side of the Body

Perhaps the most important finding of studies related to ADL intervention for hemiparesis is that the side of the lesion may predict a pattern of problems but may not predict self-care outcomes. The cognitive and perceptual problems associated with different lesion sites and extents of damage were summarized earlier.

The differences between left- and right-side brain damage do not affect prognosis for self-care independence directly. Instead it appears that clients with left-sided brain damage are easier to train, receive more training, and progress more rapidly. Clients with right-sided damage tend to be more difficult to train, take longer to train, and tend to receive less training as a result. It remains possible that attitudes and skills of therapists and the economics of medical rehabilitation may be biased toward those with left-sided brain damage. Consequently, therapists and physicians need to be aware of the implications of their decisions about intensity and duration of training for clients with right- versus left-sided brain damage. It seems especially important to note that both groups show gains over time in self-care and that the hospital discharge prognosis for ADL independence is not necessarily the long-term self-care prognosis.

Historically, many therapeutic programs for stroke concentrated on the neurologic substrates of stroke, seeking to normalize muscle tone as a precursor to emphasis on functional training. More recent controlled studies have shown that motor learning strategies may represent a more

effective approach in achieving improved outcomes in ADL (410,411).

An intervention approach known as constraint-induced movement therapy (CiMT; also forced-use therapy) has received increasing attention. This approach uses a regimen involving intensive training of the affected extremity during which the unaffected arm is constrained in a sling for much of each day. The intent is to foster cortical reorganization to recruit other areas of the brain to assume motor planning and control functions. Some encouraging results, including improvements in ADL function, have been demonstrated in clinical studies, but the approach is still viewed by some as experimental (412–416). A study used modified CiMT by adding a mental practice component and found encouraging results (417).

### Limitations in Joint Range of Motion

Problems of limited range of motion that result in difficulty reaching common ADL items are best addressed by rearrangement of living space. An occupational therapist or other health care provider making a home visit can suggest safety equipment for the bathroom, removal of obstacles that could contribute to falls, and other adaptive devices that are needed. With respect to training, an emphasis on compensatory training regarding work simplification and energy conservation techniques is needed. Principles of joint protection and energy conservation are described in Tables 9-13 and 9-14.

**TABLE 9.13 Strategies for Joint Protection**

#### Strategies for Joint Protection

Avoid positions that foster deformity

- Buildup handles on pens/keys
- Scissors/knife to open packages
- Electric appliances
- Faucet handles with levers
- Mugs, not cups, with small handles

Avoid tight gripping

- Use a sharp knife with a large handle in a sawing motion or adaptive scissors.
- Use buildup handles on cooking/mixing utensils, buckets, tools, shears, or briefcases.
- When sweeping/mopping keep handle at waist level in front of you with back straight to avoid poor posture.
- Use a flat hand to open jars or use assistive devices such as a Zim jar opener.
- Use lightweight utensils/cookware.
- Use cutting board with prongs.
- Use a flat hand to wash windows or countertops. Do not grip sponge tightly to wring water, flatten sponge against side of sink with palm to remove water.

Avoid placing excessive or constant pressure on joints

- When rising from a sitting position, use the heel of your hand to assist yourself.
- Avoid resting your chin on your knuckles.
- Avoid lifting heavy objects or repetitively gripping/lifting objects during work/ADL.
- Place heavy objects on wheels/slide them.

(Continued)

**TABLE 9.13** Strategies for Joint Protection (*Continued*)

## Avoid prolonged static positions

- During activities such as typing, reading, desk work, and sewing, take frequent breaks to rest or move joints.
- When driving a car long distances, periodically release grip on steering wheel by resting/shaking hands one at a time.
- A foam steering wheel cover allows a less forceful grip.

## Use proper body mechanics

- When lifting objects from below waist level, bend knees and keep back straight.
- Do not lift heavy/bulky objects overhead. Use a stool to reach high places.
- When using a twisting motion, always turn hand toward the thumb (e.g., turning door knobs, keys in locks, jar lids, or wringing clothes).

## Use the largest, most stable joint for the task

- Lift an object with both hands using both forearms to carry close to body instead of gripping handles.
- Push objects with your weight instead of pulling them with your fingers.
- Carry purse on shoulder or forearm rather than in hand. Lighten purse/briefcase as much as possible.

## Respect pain and fatigue

- Learn to distinguish the usual pain/fatigue that decreases after completing an activity from the pain that persists longer than 1 hr after the activity ends.
- Stop activity when signs of fatigue are noticeable.
- Eliminate activities resulting in persistent pain.
- Get enough rest: 10–12 hrs each night taking naps as necessary during the day. Rest has been shown to have a significant effect on how joints feel.
- Rest joints when they are flared-up or painful in deformity, preventing positions to prevent tightening and lost ROM.
- Learn placing techniques to accomplish what you want while keeping pain at a manageable level and to be able to do both of these things day after day.
- Use time, not pain, as guide to limit activity.
- Deformity-preventing joint resting positions in a firm bed are as follows:
  - Chest expanded
  - Small pillow used below neck/head
  - Ankles neutral using a pillow
  - Spine straight with hips extended
  - Shoulders held back with arms straight
- Knees should be extended and straight.

## Prioritize and organize activities

- Develop realistic expectations of what can be accomplished.
- Spend most of the time on enjoyable activities.
- Organize and plan for frequent rest.
- Eliminate activities that cannot be stopped if the joints get tired.
- Learn deep relaxation to release tension by meditation, music, relaxation tapes, imagery, or biofeedback.

## Exercise

- For muscle strength and range of motion
- Full general range of motion or aquatic therapy; however, isometric exercises in a pain-free ROM are best during a flare-up

**SUMMARY OF REMEDIATION STRATEGIES**

Evaluation and management strategies for promoting independence in self-care represent, from the client's standpoint, one of the most practical and important aspects of medical rehabilitation. As a rehabilitation goal, performance of BADL and EADL is now being viewed as an important outcome with profound implications for quality of life. In this chapter, emphasis has been given to the importance of client/professional collaboration in setting goals and selecting methods for managing life tasks after discharge. These options

include determining if the task is feasible, if retraining or new training is desirable, if the environment needs to be altered, if assistance needs to be provided through other people, or if ATDs, including robotics and environmental control systems, may be useful.

In this collaborative process, the client's preferences, experiences, and post-discharge living environment assume at least as much importance as the diagnosis or physical limitations. Moreover, such factors as costs of time and energy must enter into decisions about the value of various options for accomplishing daily living tasks. The active participation of the

**TABLE 9.14** Application of Energy Conservation Principles to Specific ADL

Bathing/grooming
Sit to shave or apply makeup.
Place a stool in shower/tub and chair outside tub to sit to dry/dress/undress.
Use a long-handled sponge to wash legs/feet/back to avoid bending.
Dressing
Wear loose clothing and slip on shoes.
Have one dressing area where all clothing can be reached.
Gather all clothes before dressing.
Use a long-handled shoe horn, sock aid, or reacher for donning shoes, socks, and pants.
Sit between UE/LE dressing and after dressing, if necessary.
Cooking
Prepare recipes in large quantities.
Place in separate containers and freeze extra.
Plan dinners in advance.
Utilize a big apron or cart on wheels to collect all items at one time to avoid numerous trips to the cabinet.
To prepare meal and wash dishes, slide heavy objects across countertops.
Place all frequently used items on countertop or shelves for easy access, to avoid bending or reaching.
Use paper plates or gather dishes on a cart.
Soak dirty pots/pans to make scrubbing easier.
Use a dishwasher when possible.
Housekeeping
Sit at the dryer to fold clothes.
Eliminate the need to iron by buying fabric that have wrinkle protection.
Make a shopping list or alternatively.
Have groceries delivered if possible or use a shopping cart out to car to avoid carrying packages.
Use labor saving devices when possible (e.g., dishwasher, washer, and dryer).

individual in determining a plan of care represents the desired outcome of rehabilitation. This goal is ultimately to enable the individual to participate in those activities that bring life satisfaction. When remediation is not possible, compensatory techniques might be useful. This section highlights the standard techniques used by rehabilitation professionals, often in conjunction with remedial approaches.

### Adaptation and Compensatory Strategies

When habilitation or relearning fails or is inappropriate, compensatory options remain available. In compensatory intervention, the task to be performed can be adapted or eliminated, performed by a caregiver, or modified through changes to the environment. Table 9-15 summarizes a number of specific applications to disability to adapt or compensate for skills. Prescription and training on assistive devices also enables performance on desired occupations. Adaptation requires that one evaluate a task in its entirety (418). The adaptation process requires that a client's goals, interests, and performance barriers first be identified. After identifying a specific activity to analyze, one needs to describe the tools, materials, and equipment used to complete the activity, following this a description of the typical context and space demands needed for task completion (e.g., physical space, lighting). Additionally, an analysis of

the social, communication, and cognitive requirements must be identified. Finally, a logical sequencing of the steps and the required actions will allow the rehabilitation specialist to match competencies of the client with the needed adaptations of the task (419).

One useful approach is to teach the individual to perform a task within his or her capabilities. A second strategy is to modify the environment to permit accomplishment of the task despite limitations in ability or skill. Systems or devices can be designed or acquired to enable performance, despite cognitive deficits, or diminished strength or sensation. Finally, an agent or caregiver can assist with task requirements or perform them entirely according to the requirements of the person receiving assistance.

Often a skill the client would like to perform in a normal manner can be accomplished successfully some other way. The person with bilateral above-elbow amputations may not do well at feeding using prostheses but may develop superior toe prehension and use the feet rather than the hands to eat, write, and manipulate tools. Adaptive equipment may substitute for lost or impaired abilities that limit function. The use of such devices will be discussed in the next section.

Regardless of how compensatory training is approached, the philosophical principle that should guide intervention is that there are many approaches to accomplishing the

**TABLE 9.15 General Compensation Techniques by Impairment****Weakness**

- Use lightweight objects, tools, utensils.
- Let gravity assist activities, e.g., use of wheeled carts for transportation.
- Provide external support, e.g., use of a splint or brace to support wrist, sitting down if legs are weak.
- Use an assistive device to compensate for lost function, e.g., use of universal cuff to improve grasp, if grasp is weak.
- Use assistive techniques, e.g., slide objects along a surface to transfer from place to place.
- Use power-assisted devices and tools, e.g., electric screwdriver.
- Use biomechanical principles to aid in increasing strength, e.g., decrease resistance of opening a door by installing lever handles.
- Use largest joint possible for task.
- Use assistive devices commonly available in community, e.g., automatic door openers to open doors.
- Use both hands when possible.
- Use of energy conservation techniques.

**Endurance**

- Use energy conservation techniques (see Table 9-14).
- Use lightweight objects, tools and utensils.
- Engineer matches between capabilities and activity demands.
- Use principles of joint protection (see Table 9-13).
- Sit to perform tasks, e.g., use shower or bath chairs.

**Limited range of motion**

- Use of assistive devices, e.g., dressing sticks, researchers, or sock aides.
- Eliminate need for end range activities, e.g., use of slip on shoes, or elastic shoelaces to prevent need to bend.
- Use adaptive garments, e.g., larger size, stretch fabrics.
- Use of adaptive closures, e.g., larger buttons, Velcro fastenings, zippers.
- Adaptive utensils, e.g., built-up handles, elongated handles, long straws, universal cuffs, plate guards.
- Adaptive equipment, e.g., flexible shower hose, long-handled devices, electric toothbrush.
- Safety rails for beds, toilets, and bathtubs eliminate the need to reach long distances.
- Assistive technology, e.g., computers for writing.

**Coordination**

- Provide stabilization for object being worked on.
- Stabilization of the most proximal body part so control is improved distally.
- Use assistive devices where possible to prevent movement, e.g., Dycem, non-skid surfaces.
- Use weighted or heavy utensils.
- Use adaptations to prevent lack of fine motor skills, e.g., Velcro closures for fastening.
- Use seated positioning whenever possible.
- Lever-type doorknobs and faucet handles.

**Unilateral use of body**

- Teach one-handed techniques for activities, e.g., use of adaptive one-sided dressing techniques.
- Use of adaptive devices, e.g., electric razors.
- Use shower or bath chairs to eliminate need to stand.
- Use wall mounted devices, e.g., hair dryers and jar openers.
- Assistive technology for communication devices, e.g., keyboarding for writing, use of headphone for use of phone, use of one-touch dialing.
- Utility cart or wheeled devices for transportation of objects.
- Use of electric devices, e.g., food processor for cooking.

**Low vision or blindness**

- Organize living space, to eliminate clutter, and identify a place for every item and stress need for each item to be replaced after use, e.g., utensils are kept in the same place, items in the refrigerator and in dresser drawers.
- Use organizational strategies for scanning, e.g., left to right, top to bottom.
- Hang matching clothing together.
- Use of Braille labels and/or optical scanners to distinguish labels on medication and clothing colors.
- Use of voice activated devices, e.g., Dragon Naturally Speaking for writing, books on tape, pay bills electronically.
- Use assistive devices that provide adequate tactile, auditory or kinesthetic cues.
- Use high contrast colors.
- Ensure adequate lighting in workspaces.
- Use devices to magnify workspace or work activities, e.g., magnifiers for reading.

**TABLE 9.15** General Compensation Techniques by Impairment (*Continued*)

## Impaired or absent sensation

- Instruction on prevention, using visual inspection, scanning impaired area.
- Use of temperature gauges on faucets.
- Careful handling of sharp tools should be reinforced.
- Enlarged handles on utensils and other devices may prevent excess pressure.
- Insulate any exposed pipes under sinks if client is in wheelchair.
- Prevent or eliminate any pressure to skin that is reddened and requires more than 20 min to return to the normal color.
- Modification of positioning, equipment may be needed to prevent pressure ulcers.

## Impaired cognition

- Enhanced use of memory devices, including daily medication/pill organizers, daily planners, calendars, electronic reminders, watches with programmable timers, hand-held computers, telephones equipped with frequently called numbers and emergency numbers.
- Strategies for remembering, including organized placement of objects, e.g., keys are placed in a basket at the front door.
- Develop consistent habits and routines for daily schedule, daily schedules are posted prominently with a clock in close proximity.
- Practice routines until they become automated, create a script for performance.
- Simplify tasks
- Adapt environments to eliminate distractions.
- Social support, use family, community members to remind or engage in activity.

## Chronic pain

- Use of a biosocial model of intervention (e.g., use of psychosocial strategies in conjunction with exercise and biomechanical approaches).
- Use of joint protection techniques.
- Use body mechanics (e.g., sit when possible, use largest joint to move objects, stoop using legs to lift instead of back, avoid twisting movements).
- Use assistive devices to prevent positions that exacerbate pain.

same task. Innovative alterations in task performance may allow people to do something for themselves that under other circumstances they depend on others to perform. It is characteristic of compensatory training that the end result of a client's activity, whether it is clean teeth or tied shoelaces, is most important, rather than the method used to perform the task.

The adaptation process can typically be thought of as having five steps, highlighted in Table 9-16. These tasks include task analysis, problem identification, implementation of compensation principles and proposed solutions, training

and reevaluation for fit. As in the rehabilitative or habilitative process, or in any learning or teaching situation, the task must first be analyzed to determine the demands of the activity. The demands would include both the environmental context in which the task takes place and the performance demands (e.g., reach, manipulation, mobility, communication). Problems presenting barriers to the performance can then be identified, and a match between task demands and performance limitations can be engineered.

The principles of compensation can then be applied. Solutions are proposed and problem-solving strategies modeled for the client. The solution can then be implemented, when equipment is being recommended the rehabilitation specialist needs to be a consumer advocate and understand safe application and use of the equipment. Training and practice, with variability in context are needed to ensure proper use and consistency in use (420–422). This training consists of introduction of device, choice of as natural context as possible for practice, determining the timing of the practice, providing instruction at the client's level, using good teaching strategies, and reinforcing the use of the device or strategy (371). Finally, the device must be assessed for reliability, durability, and safety. As an example for this sequence, if a client with a hip fracture is not safe to stand in the shower, a shower seat and grab bars might be determined to be the solution for safe bathing at home. The grab bars must first be made of a heavy-duty

**TABLE 9.16** General Process for Task Adaptation

- Performance of activity demand analysis, including identification of both the performance and contextual requirements needed to complete the task
- Identification of barriers to performance, specifying barriers that prevent task completion, which gives guidance to specific solutions or strategies for compensation
- Implementation of solutions, compensation strategies, or adaptive devices/equipment
- Implementing training and practice, using effective teaching strategies, in a variable context and natural context as possible
- Reevaluation of performance and assessment of safety

material to withstand repeated use at the anticipated force levels and be anchored securely in the studs. Then the therapist must determine teaching strategies that would be most helpful to his or her client, and the client might both practice in a clinical and home setting to ensure reliability in a variety of settings. The therapist might conduct an inspection of the installed device in the client's home and ensure that the client is using the device properly (369–371).

### Environmental Modifications

Both training and devices for aiding in independent self-care must be appropriate to the living space of the client. Modifications of living spaces and the architectural barriers they often impose may greatly enhance meeting ADL goals. Necessary modifications may range from minimal, in the case of rearrangement of furniture, to extensive, when apartments or homes must be specially designed for the disabled. Intermediate to these extremes are the cases in which modifications or additions to existing space and equipment may be used to enhance function.

Although it is ideal to design facilities with sufficient flexibility to accommodate access and support the activities of a population of diverse abilities, many homes and public facilities currently in use create barriers to performance and participation. One compensatory strategy to support self-care needs is to recommend modifications in existing space. During the course of a home visit and with the aim of making environments accessible, usable, safe, and negotiable, the rehabilitation practitioner can suggest many simple accommodations that can facilitate the attainment of self-care goals. Home modification assessments are often essential to determining whether a client is safe to return home.

It is useful here to provide some examples of self-care modifications that support function when specific impairments are present. When upper-extremity range of motion is limited, pots, pans, cosmetics, canned goods, and other essential daily living items can be placed out on counters rather than kept in their traditional places, which often are difficult or impossible to reach. For the client with a visual field deficit such as homonymous hemianopsia, moving the bed and furniture into the client's intact visual field when viewed from the doorway may make it easier and safer to move around the room. Of course, the view and placement of objects relative to the bed also must be strategically considered for the same reasons.

The range of possibilities for modification of living space to meet the needs of disabled people is extensive. Examples of common modifications include widening doorways, adding ramps, converting dens or family rooms into a wheelchair-accessible bedroom, and modifying door handles and flooring to improve mobility.

Resources such as the U.S. Department of Health and Human Services, Administration on Aging, *Rebuilding Together*, give explicit guidelines for many common problems (423–426). Unfortunately, lack of information usually is not what prevents clients and caregivers from effecting changes in living space. Although cost is sometimes a barrier, one study

showed that only 52% of recommended home modifications were made, with the primary reason for non-adherence being a lack of belief in the benefits of making changes. Some health care providers have attacked these problems directly by developing partnerships between governmental and community agencies to fund programs designed to eliminate architectural barriers within the home.

### Use of Assistive Technology Devices (ATDs)

The use of ATDs has as its special mission the application of technology to increase a person's performance capabilities by compensating for diminished function. Both low- and high-technology devices are available. High-technology systems are characterized by sophisticated electronic components. These include computers, robots, speech synthesizers, and environmental control systems. These electronic aids to daily living allow persons with very limited voluntary movement or degenerative neuromuscular conditions to operate a wide variety of household and workplace appliances without assistance. A study by Jutai et al. showed that electronic aids are perceived positively by clients using them and are expected to be useful by those who are not yet users but anticipate acquisition of the devices (427).

Low-technology items are simple mechanical aids, such as built-up handles for those with arthritis or shoelaces that can be tied with one hand. Such low-technology items are far more numerous than high-technology devices, yet they are sometimes overlooked. The technology of remote control has become increasingly available in modern life. For a person unable to reach a light switch, radio, television, thermostat, door lock, or curtain cord, an environmental control system can provide a new degree of independence. Ultrasonic or infrared signals, sent from a command center, may allow a person with a disability to use a variety of electronically activated appliances.

Perhaps reflecting the growth in the specialty of rehabilitation engineering, the past several decades have seen an unprecedented increase in the numbers and kinds of devices available to assist persons with functional limitations. The increase in the number of ATDs has been so significant that most rehabilitation practitioners cannot keep abreast of developments. Fortunately, in the United States, useful assistive technology databases are available to help identify suitable technologies and other information. In the United States, two federally supported web-based rehabilitation information sources currently exist, REHABDATA (428), provided by the National Rehabilitation Information Center, and ABLEDATA (429), operated under the auspices of the National Institute of Disability and Rehabilitation Research, U.S. Department of Education. ABLEDATA provides a current and searchable database describing commercially available ATDs. REHABDATA provides a broad range of information relevant to disability and rehabilitation, including devices, accessibility, programs, and research.

Research provides insight into the most appropriate strategies for deploying devices and aids to living. For example,

**FIGURE 9-4.** A long-handled shoe device can assist in dressing for persons with restricted range of motion.

studies have found that the use of assistive technology is more effective than personal care by others for reducing disability in persons with disability (430,431). Fuhrer noted the need for maturation of outcomes research in assistive technology, calling for shared databases, the development of theory for assistive technology intervention, and the implementation of a multi-stakeholder approach for outcomes research (432). Lenker and Paquet (433) propose a model to guide assistive technology outcomes research that views the acquisition and use of devices as a dynamic process that changes over time based on perceived benefits by the user. Jutai et al. (434) propose that outcomes include effectiveness, social significance, and subjective well-being. A measure validated by Sherer et al. may be useful for predicting outcomes with ATD use (435).

To determine which systems or devices each person needs, a comprehensive team evaluation leads to a list of possible solutions for each identified problem, providing ample information for the client to make the ultimate decision in the selection of equipment. In every instance, the goal of assessment is to find the simplest, least expensive device that best meets the needs for the ADL goal. Figures 9-4 through 9-7 provide examples of low-tech devices that are useful in different basic self-care tasks.

### Use of Personal Care Attendants (PCAs)

For many more people with severe disabilities, there is no combination of training, devices, or environmental modifications

**FIGURE 9-5.** A reaching device with a claw end such as this stocking aid can be used to assist with dressing.

that will enable them to function independently in self-care. For such people to live independently outside an institution, they must depend on family members for support or PCAs to assist them. Part of the rehabilitation process for people who are going to require attendant care is that they learn to recruit, hire, supervise, and, if necessary, terminate PCAs.

Often the most difficult task for the client is that of defining the tasks that require assistance, the degree of assistance

**FIGURE 9-6.** Specially designed cups can help compensate for weak palmar grasp.

**FIGURE 9-7.** Eating devices such as a built-up spoon and plate with food guard can provide valuable meal time assistance. A non-slip mat is also useful.

that is desired, and the hours of the day when these tasks need to be performed. Because hours, pay, and working schedules (i.e., often attendants are needed 7 days per week) often are not competitive with other types of employment, turnover among attendants is high. The occupational therapist or other appropriately trained health care professional often can assist the client in writing the job description for a PCA and in some cases may work with the client to be an effective supervisor. Perkinson et al. note that there are multiple options and stages for caregiving whether or not the role is assumed by family members or PCAs. They recommend the use of checklists with required tasks and procedures to assist professionals in understanding the complexities of involving family caregivers or attendants, and emphasize that ethical issues of care are not diminished simply because family members are involved in the caregiving (436).

An important and difficult aspect of working with PCAs is to be able to define all the self-care and daily living activities that will require assistance. Many tasks, such as brushing one's teeth, dressing, and grooming, are performed on a daily basis. Other tasks, such as washing one's hair or having a bowel movement, may be performed less frequently but still quite regularly. Still other tasks, such as doing the laundry or changing the bed, are even less frequent but still are performed regularly. Finally, some tasks, such as mending torn clothing or washing windows, are infrequent and not performed regularly. This list must then be categorized into three distinct classes of activities: those that the person can perform alone with or without ATDs, those that the client can perform with some assistance from others, and those that must be performed by the PCA. Research has shown that factors influencing success in the use of PCAs are mutual effort, skill, and commitment of the PCAs and employer with a disability (437).

## Disability Prevention

Disability prevention pertains to those parts of a plan of care that promote safety or prevent health problems. These strategies seek to identify risk factors and implement preventive measures before an injury or adverse health event occurs. Disability prevention can take the form of training for the client and/or the caregiver, such as in teaching joint conservation techniques for clients with arthritis or in educating clients and caregivers with spinal cord injury on methods for preventing pressure sores or complications of bowel and bladder dysfunction. Monitoring for complications such as contractures, deep vein thrombosis (DVT), or recurrent stroke following CVA is also important.

Another approach to disability prevention involves exercise to promote fitness and counter the negative consequences of a sedentary lifestyle. Using a randomized controlled trial involving elders with osteoarthritis living in the community, Penninx et al. compared an aerobic exercise program, a resistance exercise program, and a control group (receiving attention only to control for socialization effects) for their effects on ADL disability assessed during an 18-month follow-up. The cumulative incidence of ADL-related disability was significantly reduced in the exercise groups in comparison to the control group (438).

Disability prevention also takes place through the use of environmental modifications oriented toward safety, such as attention to home hazards, lighting, and the installation of handrails and bathroom grab bars. Removal of throw rugs and other common obstacles for mobility or sensory limitations may make a nighttime trip to the bathroom considerably safer. Scales oriented toward the systematic assessment of living environments for safety and accessibility have been reported in the literature.

Another important area of safety and disability prevention concerns the prevention of falls. Fall prevention may include exercise programs to improve strength and postural control, improved medication management, careful attention to the selection and use of assistive technologies, and as indicated earlier, environmental modifications to improve safety. Research has shown that foot problems, assistive technology use, dementia or cognitive deficits, and the use of medications for depression, psychosis, or anxiety are factors that increase the risk of falling (439).

## Health Promotion

A fourth intervention category involves strategies that promote health. Although some of the approaches in this category are similar to preventive strategies, because they may also serve to increase available resources of energy and time, they are considered to be health enhancing (440–443). One example of a strategy in this category is careful planning of the daily routines surrounding BADL and EADL. Conserving available energy and time in the face of competing demands makes it appropriate for the client and caregiver to determine what tasks may be better assigned to caregivers even though the client is capable of performing them with or without assistance.

## SUMMARY

Evaluation and management strategies for promoting independence in self-care represent one of the most practical and important aspects of medical rehabilitation. As a rehabilitation goal, performance of BADL and EADL is now being viewed as an important outcome with profound implications for quality of life. In this chapter, emphasis has been given to the importance of client/professional collaboration in setting goals and selecting methods for managing life tasks after discharge. These options include determining if the task is feasible, if retraining or new training is desirable, if the environment needs to be altered, if assistance needs to be provided through other people, or if ATDs, including robotics and environmental control systems, may be useful.

In this collaborative process, the client's preferences, experiences, and post-discharge living environment assume at least as much importance as the diagnosis or physical limitations. Moreover, such factors as costs of time and energy must enter into decisions about the value of various options for accomplishing daily living tasks. The active participation of the individual in determining a plan of care represents the desired outcome of rehabilitation. The goal is ultimately to enable the individual to participate in those activities that bring life satisfaction.

## ACKNOWLEDGMENT

The work of Richard Schwartz, Karin Barnes, PhD, OTR, and Kenneth Ottenbacher, PhD, OTR was instrumental to the development of earlier versions of this chapter and is acknowledged with appreciation. We also thank Charles Hayden and Sarah Gibson for valuable assistance with the present chapter.

# Disability Determination

The medical evaluation and treatment of physical impairments and associated disabilities embody the clinical practice of rehabilitation medicine. The psychiatric emphasis toward evaluating and managing the disabling aspects of illness and injury sets us apart from more traditional medical fields, whose scope and focus rest primarily on the diagnosis and treatment of pathology and medical impairment. However, the past decade has witnessed an expanding interest among general medical providers in acquiring the skills of medical impairment rating (IR) and disability evaluation. A number of organizations now offer training courses on topics pertaining to disability evaluation (e.g., the American Academy of Disability Evaluating Physicians [AADEP, [www.aadep.org](http://www.aadep.org)]; American Board of Independent Medical Examiners [ABIME, [www.abime.org](http://www.abime.org)]; American Academy of Physical Medicine and Rehabilitation [AAPM&R, [www.aapmr.org](http://www.aapmr.org)]), and a certification examination in the emerging field of disability medicine is also available to interested health care providers through the ABIME.

This chapter is intended to underscore the importance of psychiatry to disability medicine and of disability determinations to the psychiatrist's practice. Furthermore, it is intended to provide the psychiatrist with a conceptual understanding of the current disablement model, a working vocabulary of terms commonly used in disability determinations, and a comparative understanding of the similarities and differences among the major U.S. disability systems within which such determinations take place. In addition, detailed discussions are provided concerning the evaluating and reporting requirements of the independent medical examiner, the IR process, return-to-work determinations, and some of the legal/ethical challenges facing the disability examiner.

## MODELS OF DISABLEMENT

The consistency (or lack thereof) of definitions and criteria for disablement is a source of confusion immediately evident to the psychiatrist who engages in the process of disability determinations. The taxonomy and associated nomenclature of disablement vary widely, both locally and internationally. Terminologies and definitions may differ significantly between disability systems or even among jurisdictions within a particular disability system. The core concepts and theoretical underpinnings of disability as a social construct are fully discussed in Chapter 54. Nevertheless, the current reference framework for

communicating about disability is also briefly reviewed here, to provide the psychiatrist with a fundamental and common perspective from which to view the various interpretations placed on the constructs of impairment and disability within each particular disability system.

## ICF 2001

The World Health Organization (WHO) has recently adopted the *International Classification of Functioning, Disability and Health (ICF)* (1). A new terminology and conceptual model of disablement have been introduced that provide a common framework within which to view human functioning and disability from the perspective of the body, the individual, and society. *Human functioning* encompasses *body functions* and *body structures*, *activities* (personal sphere), and *participations* (societal sphere). *Disability* encompasses *impairments*, *limitations* (on activity), and *restrictions* (to participation) that may occur in the presence of a *health condition* (disorder or disease). *Contextual factors*, including *environmental* factors and *personal* factors, interact within the model as well (Fig. 10-1). Consequently, an individual's functioning and disability can be considered as the dynamic interaction of one's health condition and contextual factors in each case.

The disability examiner should become familiar with the constructs and applications of the ICF model to the field of medical disability determinations, where the validity and reliability of reporting requirements are increasingly being stressed.

In practice, however, the real-world applications of some of these terms of disablement are used differently. Workers' compensation jurisdictions and many insurance companies use *disabled* to imply that the person can no longer perform the *substantial and material duties of an occupation*. So, for example, when an individual cannot lift "twenty ton per day" (e.g., throw 400 sacks weighing 100 lb each per day), they are considered disabled for performing that particular job.

To be disabled in the context of the Social Security Administration (SSA) means that a person must be disabled for "all substantial gainful activity" (SGA) in order to receive benefits from this agency. A ballerina who crushes her great toe has most likely concluded her career as a dancer and is disabled from this occupation in the eyes of her long-term disability carrier. SSA would certainly not see her as disabled and would

**FIGURE 10-1.** Model of disablement according to the ICF. (Modified from WHO. *International Classification of Functioning, Disability and Health*. Geneva, Switzerland: World Health Organization; 2001:18, with permission.)

point out that there are a wide array of occupations to which the dancer could still potentially apply herself.

Finally, there are important modifiers to the concept of disability. Under workers' compensation, for example, if a registered nurse can no longer engage in heavy lifting, bending, and stooping on a frequent basis as required by his or her job description, he or she is disabled from his or her *regular duty* and may be restricted to *light duty*. In general, when a worker has an acute musculoskeletal (e.g., back) injury, a physician may place the patient on *temporary disability*, but it is unlikely there will be any *permanent disability*. When treatment for a particular condition has continued without improvement for more than 12 months, many would consider that the patient's *temporary disability* has become a *permanent disability*. If so, a disability rating is then required by many workers' compensation jurisdictions, and the physician examiner must determine if the patient's disability is *total* (100% of the whole person) or *partial* (some fraction thereof).

The terms impairment and disability are often used somewhat interchangeably and incorrectly. For example, physicians may be asked in certain jurisdictions (e.g., Iowa) to use the *AMA Guides* (2) to provide a disability rating although the title and introduction to the book clearly state it is intended to rate *impairment* and not disability. The reason is simple—different jurisdictions rate and provide compensation for physical impairments differently. There is no way the *AMA Guides* could satisfy the rules of disability ratings in all of these different settings.

## MAJOR U.S. DISABILITY SYSTEMS COMPARED

The major U.S. disability systems include tort claims liabilities, workers' compensation, Social Security, private disability insurance claims, and various federal disability programs.

A discussion of each of these disability systems follows. Table 10-1 compares these systems graphically (3). The reader is also referred elsewhere for more extensive and in-depth discussions of this topic (4) than is possible here.

### Tort Claims

Before the 1880s, a worker who was injured on the job could only seek redress against his or her employer by bringing civil suit under common law, where cases were decided based on legal precedent. Tort liability was applicable and implied civil wrongdoing, whereby the burden of proof rested with the claimant. A successful tort claim required proof that (a) a legal duty existed, (b) a breach of legal duty occurred, and (c) harm or injury occurred as the direct result. The employer's defense rested on grounds of employee contributory negligence, assumption of risk, and the "Fellow Servant Doctrine" implicating co-worker contributory negligence. Winning meant a large lump-sum payment for damages, whereas losing meant no reimbursement for medical expenses or time-loss compensation. The odds of winning were unacceptably low, with less than one in five claims settled in favor of the plaintiff. In their present form, tort claims often arise out of personal injury cases (i.e., medical malpractice, vehicular accidents) where criteria for recovery for damages vary by jurisdiction (5).

### Workers' Compensation

Workers' compensation arose out of inadequacies of recovery of claims under the tort system. The first workers' compensation system was introduced by Germany in 1884 (6), and the first U.S. industrial compensation system was established in Wisconsin in 1911. Other states rapidly followed suit. As a result, workers' compensation now exists in all 50 states as well as the District of Columbia (6).

In the United States, workers' compensation law is determined on a state-by-state basis. Each state has its own compensation system, and there are significant differences from one system to another. In general, though, compensation systems share the following common features (3):

1. The system is no-fault, and the employer assumes liability for all claims arising as a result of injury or illness directly attributable to the workplace. In return, the worker gives up the right to bring suit against the employer for separate damages in most circumstances except where wanton negligence applies.
2. Benefits are provided only for work-related conditions that are medically determined to arise directly out of and in the course of employment. Causality is established by demonstrating that a compensable condition occurred while the employee was at work and engaged in employment activity.
3. An employee may forfeit eligibility if he or she was intoxicated or engaged in unsafe practices at the time of injury or if he or she was incarcerated or refused to return to work after being cleared medically to do so.
4. The condition must persist beyond a statutory waiting period (typically 7 days).

**TABLE 10.1** Major U.S. Disability Systems Graphically Compared

	Workers' Compensation	Social Security	Disability Insurance	Federal Employees' Compensation	Longshore and Harbor Workers' Compensation Program	Railroad Workers and Seamen	Black Lung Benefits	Veterans Disability Programs
Eligible individuals	Nonfederal workers injured out of and in the course of employment	Workers <65 or survivors who are or have contributed to the SS Trust Fund (SSDI), needy disabled children, aged, and blind (SSI)	Those covered by a group or individual long-term disability plan after a period of short-term disability defined by the policy	Federal employees, including U.S. postal service	Maritime employees such as seamen, longshoremen, harbor workers, shipworkers (not seamen)	Railroad workers and seamen	Coalminers	Honorable or general discharge from the armed forces or a survivor of a veteran
Adjudicating body	Individual state workers' compensation statutes	Social Security Administration	Long-term disability carrier	Office of Workers' Compensation Programs in the U.S. department of labor	Office of Workers' Compensation Programs in the U.S. department of labor	Railroad Retirement Board	Office of Workers' Compensation programs in the U.S. department of labor	Adjudication Division of the Compensation and Pension Service of the Veterans Benefits Administration
Rating schedule	AMA <i>Guides</i> in many states; special schedules in FL, MN, CA	Disability Evaluation Under Social Security (Listing of Impairments)	None	AMA <i>Guides</i>	AMA <i>Guides</i>	None	CXR, PFTs, ABGs, and physical examination	Physician's Guide for Disability Evaluation Examinations
Employability status	Unable to work in one's own occupation or in lighter duty, if available	Unable to engage in substantial gainful employment that pays \$500/month for >12 months	Inability to engage in own occupation up to 2 years or in any occupation, thereafter, depending on the individual plan	Loss of earnings (no schedule loss) due to disability resulting from personal injury sustained while in the performance of duty	Wage loss and schedule loss benefits for injuries arising out of and in the course of employment	Sickness and unemployment benefits from the Railroad Retirement Board	Total disability due to pneumoconiosis	Wage loss and schedule loss for the average person unable to follow a substantially gainful occupation
Benefits	Survivor benefits, medical and rehabilitation expenses, wage loss benefits. Tort immunity for the employer	Monthly stipend	Wage compensation	66.6%–75% of wages, reasonable medical care. Lump sums not available	Full medical care, death benefits, lump-sum awards, 66.6% of weekly wages	Railroad workers and seamen must pursue action for damages under the Federal Employers' Liability Act		Disability pension, death benefits, hospitalization, medical care, orthotics, prosthetics, durable medical goods, adaptive modifications \$1989 as of 1999
Maximum monthly benefit	Determined by state statute		Generally 60%–70% of employment income	75% of wages if worker married or has dependents	200% of the current national average weekly wage			

SSI, supplemental security income; SSDI, social security disability insurance; CXR, chest x-ray; PFTs, pulmonary function tests; ABGs, arterial blood gas. Reprinted from Rondinelli RD, Katz RT, eds. *Phys Med Rehabil Clin N Am*. 2001;12:500, with permission.

**TABLE 10.2** Coverage Under Workers' Compensation

Medical expenses: all acute, most chronic, some other (e.g., YMCA to swim), medical supplies, psychological, some travel; employer insurer must accept an injured worker "as is" (must cover exacerbation of preexisting emotional problems)
Short-term disability beyond specified interval (3–6 d)
Permanent disability assessed when
(1) Individual returns to work
(2) Maximum healing has occurred
Rehabilitation services (some states only)
Some states allow employer/carrier to choose the doctor, others allow employee complete choice
Insurance carriers always have right to obtain an IME

5. A claim must be filed within a specified time period. In general, the employer must be notified within 30 days of illness or injury, and a claim must be filed within 1 year of illness or injury or within 2 years if death is the result.
6. Disability may be temporary or permanent, partial or total.
7. Benefits under workers' compensation include survivor benefits in case of death, medical and rehabilitation expenses, and wage-loss benefits (generally, two thirds of wages) during the period of temporary disability. Table 10-2 summarizes coverage/benefits under workers' compensation.

Many states have adopted a *second injury fund* to encourage employment of individuals with preexisting disabilities, whereby the employer is protected from excess liability for compensation due to preexisting conditions. The second injury fund in Missouri, for example, began after World War II, when employers were encouraged to hire wounded veterans. The principal concept of a second injury fund is to compensate injured parties for the "synergistic" effects of prior and present injuries. For example, if a worker who had previously been blinded in one eye suffered loss of vision in the second eye, the impairment and disability would be much greater than twice the value of the first eye. This compensation for the "synergistic" or "combined" effect of two injuries is the principal intent of a second injury fund. Readers should investigate further by consulting the statutes in their particular state or jurisdiction.

### Social Security Disability Insurance and Supplemental Security Income

The SSA is the largest U.S. disability program, assisting between one third and one half of those persons qualified as disabled (7). It includes the following two separate disability programs:

- Social Security Disability Insurance (SSDI) was established in 1956 to assist workers more than 50 years of age who became totally and permanently disabled. It is funded according to the Federal Insurance Contribution Act (FICA) payroll

tax, combining deductions for old age and social disability insurance (OASDI). In general, workers are eligible if they are less than 65 years of age and if they have worked in a job covered by SSDI for at least 5 of the 10 years immediately preceding onset of disability. A requisite criterion of disability determination is proof that the individual is unable to engage in any SGA by reason of any medically determinable physical or mental impairment that can be expected to result in death or that has lasted or can be expected to last for a continuous period of at least 12 months (8). Beneficiaries of SSDI can exit the system by death, by reaching age 65, by undergoing continuing disability review (CDR) in which significant medical improvement is determined such that the individual is no longer eligible for disability, or by returning to work. Less than 5% of beneficiaries "fail" CDR and/or eventually return to work (8).

- Supplemental Security Income (SSI) was established in 1972 to provide support for indigent people who were blind, disabled, and less than 65 years of age. SSI operates as a federal-state partnership funded by general revenue (i.e., federal and state income tax). Individuals are eligible even if they have never worked, if they can be shown to have low income/assets (through "means testing"), and if their medical condition is severely incapacitating such that they cannot engage in SGA, according to the same criteria as SSDI (8).

Benefits to recipients of SSDI or SSI are primarily in the form of monthly stipends. However, recipients of SSDI become eligible for Medicare benefits after 24 months of entitlement. Similarly, recipients of SSI automatically become eligible for Medicaid. In some cases, recipients of SSDI who also meet means test criteria for Medicaid are entitled to both types of coverage (8).

### Private Disability Insurance

Approximately 40 million Americans have private long-term disability coverage, usually available through the workplace. Policies may be individual or group. Group policies are typically made available through the employee's company and are more affordable. Definitions of disability and criteria for entitlement vary and are stipulated by contractual language rather than mandated by statutory provisions. Typically, employees who become disabled for their usual and customary occupation are covered by short-term disability for an initial period of 90 days, after which their long-term disability policy takes effect. In general, the duration of coverage is finite and specified (typically 2 years). Subsequently, the disabled person will continue to receive benefits only if unable to perform the functions of any occupation as provisionally defined (5).

An important feature of long-term disability policies is whether there is *own occupation* versus *any occupation* coverage. Own occupation coverage provides the insured with disability benefits (typically in the range of 60% of normal salary reimbursement to provide incentive to return to work) if they are not able to provide the essential elements of their particular job. Thus, a neurosurgeon would receive reimbursement if

no longer able to perform surgery, even if other physician responsibilities could be completed. Any occupation coverage means, within limits, the employee would be reimbursed only if he or she could no longer perform meaningful work in any related occupation. Again, the criteria vary according to the insurer. Less expensive *group* long-term disability plans tend to have own occupation coverage for approximately 2 years, and then the worker must be disabled from any occupation to receive further benefits. More expensive *individual* long-term disability plans tend to have more restrictive own occupation provisions.

### Federal Employees Compensation Act

The Federal Employees Compensation Act (FECA) provides compensation benefits to civilian employees of the federal government for work-related disability. Coverage extends to federal employees of the U.S. Postal Service and Peace Corps, and certain nonfederal employees, including state and local law enforcement and the Civil Air Patrol. It is a no-fault system, so that federal employees cannot sue the federal government or recover damages under any other statute for work-related injuries (5).

### Longshore and Harbor Workers Compensation Act

The Longshore and Harbor Workers' Compensation Act (LHWCA) provides benefits to shoreside maritime employees such as shipbuilders and repairmen. It is a no-fault system administered by the U.S. Department of Labor (5).

### Federal Employers Liability Act and Jones Act

The Federal Employers Liability Act (FELA) provides disability benefits to employees of the interstate railroad industry. It is a potentially adversarial system reminiscent of tort claims liability, insofar as the claimant can file suit in either federal or state civil court and must prove negligence on the part of the railroad. The employer's defense is limited to comparative negligence, whereby recovery for damages may be proportionately reduced according to percentage of employer versus employee culpability.

The Jones Act is similar to FELA but covers civilian sailors for permanent disability suffered while in the service of a ship on navigable waters. The claimant must file suit against the ship's owner, and cases are often settled out of court (5).

### Federal Black Lung Program

The Federal Black Lung Program provides coverage for coal miners engaged in surface or underground activity, for total disability caused by pneumoconiosis (black lung) arising from employment. Diagnosis is ascertained through specific chest x-ray findings confirmed by certified "B-readers" according to National Institute of Occupational Health and Safety (NIOSH) standards and the International Labour Organization classification system. Disability claims are referenced according to U.S. Department of Labor standards for spirometric and arterial blood gas measurements (5).

### Department of Veterans Affairs

Veterans who have received an honorable or general discharge from active military duty are eligible for compensation and pensioning within the Department of Veterans Affairs (VA). Entitlement is considered service connected if the disabling condition is due to illness or injury incurred or aggravated during the period of active duty. Non-service-connected entitlement refers to conditions determined to be unrelated to the period of active duty (9). Benefits include disability pensions for service-connected disability as monthly payments to the veteran or spouse/surviving children in the event of death, hospitalization and medical care, orthotic and prosthetic devices, durable medical equipment, and adaptive modifications to home and/or motor vehicle to accommodate disability (5).

## PREVALENCE AND COSTS OF DISABILITY

The prevalence of disability varies widely in different western countries. For example, the United States, Canada, and Great Britain each have a prevalence of approximately 2% to 3%, West Germany and the Netherlands 4%, and Sweden has climbed to an astonishing 8% of the population. In Britain, the disability rates for chronic low back pain (LBP) are increasing exponentially (10). Our system of social justice dictates that those who are disabled due to severe or catastrophic impairments (e.g., head injury, spinal cord injury, severe multiple trauma) are deserving and in need of a "safety net" of financial and other assistance. However, there are many patients who seek disability support from this same social safety net, often without any clear pathology (e.g., with LBP). If 8% of the working-age population is on disability (many of these due to LBP), this places a huge burden on the remaining persons in the work force. The prevalence of work disability in the United States by state has been summarized in a recent report. In 2001, the U.S. Census Bureau estimated that there was a resident population of 176,953,784 in the United States between ages 18 and 64; 3.4% of these were disabled. West Virginia, Mississippi, and Kentucky had the highest rates (6.8%, 6%, 6%, respectively), while Utah and Alaska had the lowest (2.0% and 2.1%, respectively). (Source: Disabled Beneficiaries and Dependents Master Beneficiary Record file U.S. Census Bureau, 2001 estimates.)

The costs to society of this "wealth of disability," much of it related to LBP, are simply staggering (11). They include medical expenditures, lost wages, lost production, consumer cost increases, employee retraining, and litigation. The costs of workers' compensation claims by case in 2002 varied from \$21,087 in California to \$3,959 in Wyoming. (Source: National Council on Compensation Insurance. Public Policy Institute of NYS, Inc., 152 Washington Avenue, Albany, NY 12210 [http://www.ppiny.org/reports/jtf2004/workerscomp.htm].) Medical costs previously made up roughly one third of workers' compensation costs but now make up greater than 55% of total losses (National Council on Compensation Insurance data).

Clearly, the financial stakes and clinical implications of medical disability evaluation and reporting are enormous and require much diligence, preparation, and adequate training on the part of the community of involved medical practitioners. This will help to ensure that claims are handled as competently, straightforwardly, and compassionately as possible and with attention to the fair representation of the interests of all parties including claimants, employers, insurers, and adjudicators alike.

## PHYSICIAN EVALUATING AND REPORTING REQUIREMENTS OF THE INDEPENDENT MEDICAL EXAMINATION

In cases of industrial injury where a legal claim dispute arises, the claimant or insurer or a neutral party (often an administrative law judge) may engage the services of an impartial physician to render an *independent medical examination* (IME) for purposes of determining disability. The disability examiner performing an IME *must not* have prior familiarity with, or direct involvement in, the case at the time of referral. The disability examiner is expected to represent the interests of all parties to the dispute fairly and impartially and therefore cannot be the treating physician of record.

The physiatrist acting as disability examiner for purposes of an IME can typically be expected to address the following issues in the evaluation and report (12).

### Diagnosis and Severity

What is the diagnosis and extent of severity of the condition in question? The disability examiner must review available treatment records and perform a detailed history and physical examination pursuant to the presenting complaint(s), in order to identify and appropriately document objective pathology and supportive findings. Additional diagnostic tests or procedures may be requested and authorized to render a diagnostic impression and do not by themselves denote a treating relationship.

### Prognosis

What is the probability of improvement or resolution of impairment, and what residual symptoms or loss of function is expected?

### Causality

What is the cause of the condition? *Causality* refers to the association between a given cause (event capable of producing an effect) and an effect (a condition that can result from a specific cause) within the medical probability. *Medical probability* is the physician's estimate that something is more likely than not (likelihood of causation exceeds 50%), as opposed to *medical possibility* (likelihood of causation is equal to or < 50%). Typically, a work-related injury must be shown to have a *proximate* cause whereby a direct and unbroken sequence of events

produced the condition, without which cause the condition would not have occurred (13). Judgments regarding causality are typically not difficult when a previously healthy worker experiences a clear-cut injury with obvious clinical findings. However, they can be quite challenging when a worker has a history of problems in the currently affected area or when the alleged cause of symptoms is cumulative trauma rather than a single event (14). A careful history is of paramount importance to the determination of causality and should identify the circumstances and events during which injury occurred, documenting any previous injuries, treatments, and preexisting impairment or dysfunction and identifying important psychosocial contributing factors if applicable. In cases of occupational illness, as opposed to injury, such conditions (e.g., carpal tunnel syndrome, cumulative trauma disorders) may be regarded as arising proximately out of employment. Accordingly, the history should focus on occupational activities and risk factors, and outside recreational activities of a repetitive nature should be noted (13).

### Necessity and Appropriateness of Diagnostic Testing and Treatments Rendered

Have the necessary diagnostic tests been performed? Has the treatment rendered been medically necessary, effective, and appropriate in terms of intensity, frequency, and duration? The disability examiner should ensure that a sufficient and thorough diagnostic workup and treatment period have been provided.

### Additional Diagnostic Testing and Treatments Needed

What additional diagnostic and medical or therapeutic recommendations might improve outcome and hasten recovery? The disability examiner may recommend additional tests and treatments but should avoid contributing to the development of an “illness conviction” mindset through an endorsement of excessive diagnostic inquiries or inappropriate and perhaps futile treatment efforts. Only those treatments with reasonable expectation of further reducing the objective impairment and/or improving function should be endorsed.

### Maximum Medical Improvement

*Maximum medical improvement* (MMI) is the point when a medical impairment becomes stable, so that additional diagnostic tests and/or therapeutic interventions are not reasonably expected to produce further improvement (2). MMI is felt to have occurred when a “sufficient healing period” has elapsed (the *AMA Guides* previously recognized 6 months as a sufficient healing period; the fifth and subsequent sixth edition no longer specify the duration of sufficient healing), when the medical condition has resolved, or when there is no reasonable ongoing or anticipated progress toward resolution of the condition. From a physiatric perspective, this end point is reached when the impairment is judged stable such that additional physical and functional improvements are no longer tenable (i.e., “maximum functional improvement”). Consequently,

an MMI determination should be based primarily on lack of demonstrable progress toward reducing impairment or achieving measurable functional gains, rather than symptom reduction *per se*.

Sometimes a patient meets criteria for MMI when the condition is no longer improving but is expected to deteriorate over time. An example would be a fracture into a joint. In this situation, the physiatrist can still declare the patient to have reached MMI. The issue of long-term deterioration is handled in either of two ways, depending on the patient's compensation system. One method requires the physiatrist to provide an estimate of the patient's future medical needs to maintain stability and/or to minimize progression of impairment regarding the condition. The other is to identify that the patient has reached MMI and is ready for claim closure but to note that a reopening of the claim might be necessary and appropriate at a future date.

### Impairment Rating and Apportionment

What is the permanent IR? The permanent total or partial physical impairment associated with the condition should be determined according to methods and procedures outlined in the *AMA Guides* (2), where permitted by law (see below). Jurisdictional rules and reference systems may vary, and the disability examiner must comply with local requirements or risk judicial impeachment of his or her medical opinions and conclusions otherwise rendered.

### Return-to-Work Restrictions

Can the injured worker return to the former job and, if so, how soon? Job description, job analysis, and functional capacity evaluation (FCE) can assist the disability examiner in determining fitness for duty following work injury (see later). When valid performance measurements are available, those data should guide the physiatrist's estimate of ability of an injured worker to perform the essential functions of the job safely and effectively. When performance is invalid because of inconsistencies and submaximal effort, the physiatrist's assessment becomes increasingly subjective and conjectural.

## MEDICAL IMPAIRMENT RATING

### Purpose and Derivation of the *AMA Guides*

The *AMA Guides* (2) has been developed as a standard reference to assist the physician in evaluating and reporting medical impairment of any human organ system. The estimates derived according to the *AMA Guides* are generally applicable to disability claims evaluations under workers' compensation and some private disability systems. In the United States, the *AMA Guides* is currently used by 44 states, 2 commonwealths, and federal employee compensation systems (in about 90+% of U.S. jurisdictions), as required by statute, regulations, or administrative/legal practice in workers' compensation cases (2). Under workers' compensation law, physician input is mandated to the

determination of causality and the coordination and direction of medical care, MMI determination, IR, and return-to-work release and/or restrictions. The *AMA Guides* has undergone periodic revisions since its inception in 1971. The sixth edition is the current and preferred edition; however, prior editions are still in use and mandated in some jurisdictions. Readers are encouraged to become familiar with the laws and requirements of the particular jurisdiction in which they practice and to comply fully with prescribed guidelines and reference materials locally available.

### Limitations of the *AMA Guides*

The impairment percentages listed according to the *AMA Guides* are intended to represent an informed estimate of the degree to which an individual's capacity to carry out daily activities has been diminished (2). The *AMA Guides* provides a disclaimer that it is not to be used for direct estimates of work disability (2). Despite this, impairment percentages derived according to the *AMA Guides* are frequently used directly to determine disability percentages for work loss compensation purposes.

Subjectivity on the part of the claimant and/or examiner, as well as consistency of effort put forth by the claimant, may skew or otherwise affect the reliability of impairment measures (15,16). The physician examiner can frequently expect to encounter elements of symptom magnification, particularly in the presence of chronicity and pain. Exaggerated displays of pain behavior and related inconsistencies should be noted and documented; when properly accounted for, they should not result in inflated IRs or in inappropriate penalizing of the claimant who exhibits them.

The conceptual issues surrounding the definition of pain and measurement of pain behavior are well documented (17). Detailed discussions of the relationships between pain and suffering (18) and pain and disability (19) are presented elsewhere, and the reader is referred to Chapter 24 for a more detailed discussion of pain issues. For purposes of the IR process, the experience of pain is not directly and objectively measurable. The relationship between pain and suffering is essentially subjective. In general, pain behavior should not serve as the sole basis for an IR in the absence of objective corroborative findings.

### The Musculoskeletal System

Space limitations preclude a fully detailed review of the IR process and guidelines for each organ system. Because the physiatrist typically deals with impairment and disability directly pertaining to the musculoskeletal system, certain details and key points related to musculoskeletal IR are highlighted here. The reader is referred to the *AMA Guides* (2) for the most current, detailed, and expanded discussions of other organ systems, particularly the cardiopulmonary and respiratory systems.

Impairments affecting the musculoskeletal system are generally viewed in terms of three regional units (i.e., the upper extremity, the lower extremity, and the spine). Medical impairment is assessed independently for each of these units. The upper extremity is further divided into regional subunits

of thumb/finger/hand, wrist, elbow, and shoulder. The lower extremity is divided into three subunits to include the foot and ankle, knee, and hip. The spine and pelvis are divided into cervical, thoracic, lumbar, and pelvis subunits. Within each regional unit, impairment is calculated for the smallest applicable subunit. Separate impairments within a subunit are added before impairments between subunits are combined within a region. Similarly, individual impairments within a region can be combined between regions. When two impairment values are combined within or between regional units or subunits, the smaller value (*B*) is combined with the larger value (*A*) by the following formula (2) whose combined value (*C*) is

$$C = A + B [1 - A]$$

This adjustment is necessary so that the cumulative impairment for a series of regional units or subunits does not exceed 100%. A reference table of “combined values” is provided to facilitate these conversions (2). If requested to do so, the disability examiner can convert impairments of the upper extremity to a “whole-person” estimate by multiplying by 0.6; similarly, impairments of the lower extremity can be converted by multiplying by 0.4. Impairment of the spine is always determined to the “whole person.”

### The “Diagnosis-Based Impairment” Model

In an effort to enhance precision of IRs and increase interrater agreement and to improve upon the evidence base for IRs, the most recent AMA *Guides* (2) has become more diagnosis based, with the diagnoses themselves being more evidence based. This “diagnosis-based impairment” (DBI) method employs a common grid format with five columns for successive impairment classes 0 to 4 and rows corresponding to commonly accepted diagnoses (2) arranged hierarchically in aggregates of soft tissue, muscle-tendon, and bone-ligament-joint pathologies. For each anatomical region, the grid specifies the diagnostic criteria, which must be fulfilled to identify the proper impairment class for a given condition, and the range of impairment rating IR available for that class and diagnosis. Once the diagnosis and IC are determined, a “severity grade” and specific IR within class is further determined by an iterative process, using specific information from the claimant’s functional history, physical exam, and associated diagnostic test results. This new approach integrates information from the traditional physical exam such as range of motion (ROM) where applicable, without placing undue weight upon such measurements, which can be time-consuming to obtain and are often prone to influence of claimant and examiner subjectivity. Furthermore, the functionally based history, although also subjective, can be sufficiently validated by simple additions to the in-office exam and does provide some new level of sensitivity to the impact of impairment on activities of daily living (ADLs).

### Deviating from the AMA *Guides*

The AMA *Guides* is intended to be just that—guides to aid the physician in analyzing and reporting data concerning medical

impairment. However, in some cases (e.g., pain), objective and reliable data are lacking; in others, adequate normative data concerning function are unavailable. In such cases, the judgment and consensus represented by the AMA *Guides* are not intended to supersede the individual rating physician, who is expected to exercise independent judgment and go beyond the boundaries and limits specified by the AMA *Guides* when the situation warrants.

## WORK DISABILITY DETERMINATION AND THE AMERICANS WITH DISABILITIES ACT

Medical impairment may affect *employability*—the capacity to meet the demands and conditions of employment set forth by an employer. Employability requires the physical capacity to travel to and from the job site, to be present at the job site for a sustained period of time, and to perform a predetermined array of tasks and duties in exchange for wages. Knowledge of medical impairment *per se* may not be a necessary or sufficient criterion for determining employability, and the physiatrist making such determinations must also be aware of and consider other criteria and perspectives offered including the Americans with Disabilities Act (ADA) (20).

Under Title I of the ADA, individuals with disabilities are afforded protection against discrimination in the workplace for private businesses that employ 15 or more persons (20). Accordingly, employability can be viewed in terms of a formal *job description* (typically available from an employer upon request) that lists the *essential functions* and associated physical task demands for that specific job. The essential functions are fundamental job duties that, if removed or altered, would change the nature of the job itself. Failure of the employee to perform the essential functions could result in termination for cause. *Accommodation* involves modification of a job description or workplace to enable an employee with an impairment or disability to otherwise meet the essential functions. The ADA mandates the availability to the disabled of *reasonable accommodation* (i.e., one that can be accomplished without posing *undue hardship* on the employer [in terms of added costs or logistic difficulties] or a *direct threat* to the health and safety of the disabled employee or any coworkers) (21).

For example, a patient with a herniated nucleus pulposus treated conservatively within the last 3 months now applies for a job that requires lifting seventy pounds, 50 times per day. Most physicians would feel comfortable that the worker would not be physically able to perform the job without a direct threat to his own health, and hopefully if the worker sued, the court would uphold the company decision. Similarly, if a worker had an uncontrolled seizure disorder, and the job required him to operate a cherry picker, which held other workers, most would agree the risk of seizure while operating the machine would be a direct threat to the workers in the compartment.

**TABLE 10.3** ADA Concepts of Work Disability and Reasonable Accommodation

Impairment	Job Category	Sample Essential Functions	Essential Functions Performed	Accommodation Needed	Reasonable Accommodation Afforded	Work Disability Present
Partial hand amputee (dominant)	Construction worker	Operates heavy equipment	+	–	Not applicable	–
	Policeman	Proficiency with hand gun	+	+++	+ (Reassign as dispatcher)	–
	Concert musician	Live concert appearances	±	+++	+ (Provide synthesizer for studio performance)	±
	Surgeon	Operates on chest	–	+++	– (Physician extender not feasible)	+

ADA, Americans with Disabilities Act.

At present, the ADA concepts and mandates have not been fully integrated into workers' compensation law and instead represent a separate and parallel system. However, the physiatrist may render an ADA-compatible return-to-work determination for an impaired worker that specifically addresses essential functions and employer willingness or ability to accommodate in each case. In essence, work disability can be operationally dealt with in relation to medical impairment, essential job functions, and options for reasonable accommodation as the following scenarios that Table 10-3 illustrates.

Assume an injured worker suffers permanent impairment as a result of partial amputation of the dominant hand. The impact of this defined impairment on disability has a wide potential range, depending on whether the employee is, for example, a construction worker, police officer, concert musician, or surgeon. If the job requires the safe operation of heavy equipment at a construction site and the worker can perform the essential functions without accommodation, no work disability is present. If the job requires the ability to safely and reliably handle small firearms, accommodation may be required and may necessitate reassignment to a dispatching operation. With that accommodation, no work disability is present. If the job involves live concert performances, the individual may be unable to meet the essential functions but may still be able to compose and deliver studio performances through the use of an electronic synthesizer or other suitable equipment. In this case, some degree of work disability is present in spite of reasonable accommodation. If the job requires a high degree of manual dexterity, such as surgery, accommodation might involve use of a surgical assistant or physician extender to provide intraoperative manual assistance. However, medicolegal and financial constraints might pose sufficient logistic barriers to preclude such accommodation (even if available); consequently, work disability is present.

### Functional Capacity Evaluation

FCE is a systematic, comprehensive, and objective measurement of an individual's maximum work abilities (22). The components of the FCE include

1. Generic testing of workers' capabilities as defined by the *Dictionary of Occupational Titles* (23).
2. Job evaluation to assess the occupational and material handling requirements of a particular job according to the job description.
3. Work capacity evaluation of ability to safely and dependably perform and sustain job-related activities in response to specific job demands (13,24).

FCE generally includes tests of strength, flexibility, endurance, coordination and reaction speed, functional performance, and safety. Functional tests include material handling (e.g., lifting and carrying, pushing and pulling), sitting, standing, walking, reaching, stooping, crouching, balancing, and climbing. In some cases, hand activities to assess grip strength, manipulation, and dexterity are included. These parameters are quantified in terms of weight and frequency. Terms used to modify frequency include *occasional*, which generally refers to  $\leq 33\%$  of the time during the work day; *frequent* or 34% to 66% of the work day; and *constant or frequent*, which is 67% or more of the work day. Strength requirements for any occupation can be placed into categories varying from *sedentary* to *very heavy* work, as described in Table 10-4.

An FCE is typically administered by a trained physical or occupational therapist, and choice of equipment for FCE testing should be driven by considerations of safety, reliability, validity, practicality, and utility in each case. The validity and reliability of test results are limited in the presence of submaximal effort. The availability and feasibility of FCE testing are often limited by cost

**TABLE 10.4** Strength Requirements Classification

Degree of Strength	Amount of Lifting/ Carrying	Posture; Other Activities
Sedentary work	Occasional: $\leq 10\#$	Primarily sitting; walking and standing at most occasionally
Light work	$\leq 20$ , $\leq 10\#$ frequently	Significant walking/standing <i>or</i> primarily sitting but requiring pushing and pulling of arm and/or leg controls
Medium work	$\leq 50\#$ , $\leq 20\#$ frequently	Unspecified
Heavy work	$\leq 100\#$ , $\leq 50\#$ frequently	Unspecified
Very heavy work	$> 100\#$ , $\geq 50\#$ frequently	Unspecified

This chart is based on the United States Department of Labor System for classifying general strength of the occupations described in the *Dictionary of Occupational Titles* (1977 and supplements).

considerations (13). Because most tests have the potential to cause harm, procedural rules with exclusionary and performance guidelines must be followed (24). The evaluator is urged to obtain signed and informed consent before carrying out the FCE.

Although FCE may be useful to determine if an employee is capable of returning to work without reinjury, the FCE cannot predict whether or not reinjury will occur (25). Nevertheless, it may be useful for the physiatrist to obtain an FCE and valid job description on which to base medical opinions concerning fitness for duty and the match between worker abilities and the essential functions and associated physical demands of the job. Figure 10-2 illustrates an integrated approach to job analysis and FCE, allowing the therapist and/or vocational analyst to compare and report worker fitness relative to a variety of job-specific task demands. Such information is most valid when full performance effort is given. It is highly relevant to the question of job-specific work disability and can be invaluable to the physiatrist seeking to minimize risk yet encourage maximum work opportunity for the returning worker. In the event that demonstrated worker's ability does not parallel job demands, the physiatrist should impose restrictions according to demonstrated performance.

The employer is responsible for determining reasonable accommodation and may be assisted by the coordinated efforts of the therapist, ergonomist, and vocational analyst as the situation warrants. It is not the responsibility of the physiatrist to determine the essential functions of the job, to devise accommodation, or to determine reasonableness of any proposed accommodation (25).

## TREATING, RATING, AND TERMINATION-OF-CARE ISSUES

The conflicts inherent to the roles of treating versus rating physician have been previously documented (26) and are summarized briefly as follows: The treating physician acts primarily as a patient advocate and seeks to diagnose and treat in order to minimize suffering. In treating the injured worker, the physician may prioritize symptom alleviation and functional recovery ahead of return-to-work considerations. Case termination becomes an objective only after medical impairment is minimized and return to work, when feasible, has been achieved. By contrast, a rating physician may face an inverse set of priorities, whereby end points of IR and work disability determination are the primary objectives of the referring party. Case termination is of paramount importance in order to enable a rating to occur (see MMI determination), and return-to-work considerations are a priority objective to enable case closure. Satisfactory diagnostic and therapeutic results are of interest in promoting successful return to work. The physiatrist, as treating or rating physician, can bridge this conflict and perform both roles equally by maintaining a priority focus on functional improvement. Diagnostic evaluations and medical and rehabilitative treatments remain viable objectives as long as functional improvement during treatment can be demonstrated. When functional improvement is no longer tenable, case termination is warranted, and an IR and work disability determination can be made. If further care of a "non-restorative" nature appears indicated beyond case closure, the physiatrist may advocate for treatment outside the workers' compensation system through alternative legal and administrative channels. It is thereby possible for the injured worker and physiatrist to maintain a functionally based therapeutic alliance throughout their course of interactions.

## Legal and Ethical Considerations

Medicolegal aspects of rehabilitation medicine are discussed in detail in Chapter 21, to which the reader is referred for discussion of expert witness testimony and related issues. It is important to note that medicolegal accountability by physicians continues to increase for their opinions rendered with respect to workers' compensation disability and IMEs. The physiatrist can expect to be frequently deposed or offer courtroom testimony regarding findings and opinions pursuant to a disability determination and may be held accountable for details recorded months or even years previously. Consequently, data collection, organization, and reporting should be carried out in a thorough, systematic, and sufficiently detailed manner to facilitate retrieval of specific information at any future time.

The disability-evaluating physiatrist must embrace a sphere of concern beyond patient advocacy to also include the interests of the employer and insurance carrier alike. Pressure may be applied to terminate treatments that are primarily palliative in nature, to hasten the injured worker's return to work or

disincentives to recovery that tend to promote disability. Furthermore, physician actions (regardless of intent) that enable excessive or inappropriate diagnostic and therapeutic efforts, or result in prolongation of claims, may help to confirm a “disability conviction” on the part of the patient, further impeding functional recovery. The difficult questions concerning terminating treatment, rating impairment, and determining work disability must be handled with finesse and dexterity and, above all, with the fairness, objectivity, and consistency that a functionally oriented focus can provide. Such complex decision making should be routinely predicated on a sound understanding of the functional implications of a particular occupational illness or injury, and a firm commitment to achieving the highest possible functional outcome in every case.

## GLOSSARY

**Disability.** An umbrella term for impairments, activity limitations, and/or participation restrictions in an individual with a health condition, disorder, or disease.

**Impairment.** A significant deviation, loss, or loss of use of any body structure or function in an individual with a health condition, disorder, or disease.

**Impairment evaluation.** Acquisition, recording, assessment, and reporting of medical evidence, performed by a licensed medical doctor or surgeon, using a standard method such as described in the *AMA Guides*, to determine permanent impairment associated with a physical or mental condition.

**Impairment rating.** Consensus-derived percentage estimate of loss of activity, which reflects severity of impairment for a given health condition, and the degree of associated limitations in terms of ADLs.

**Independent medical examination (IME).** A usually one-time evaluation performed by a licensed medical doctor or surgeon who is not treating the patient or claimant, to answer questions posed by the party requesting the IME.

# Applying the ICF in Rehabilitation Medicine

## INTRODUCTION

Functioning is the lived experience of people (1). It is a universal human experience (1,2) in which body, person, and society are intertwined (3,4). Over the life span, people may experience a variation in the level of functioning associated with congenital disorders, injuries, acute and chronic health conditions, and ageing. The experience of a limitation of functioning or disability thus is part of the human condition (1). The WHO estimates that as many as 500 million healthy life years are lost each year due to disability associated with health conditions. These are more than half the years that are lost annually due to premature death (5). This figure is increasing not only due to population growth, medical advances, and the ageing process but also due to malnutrition, war, violence, road-traffic, domestic, and occupational injuries, and other causes often related to poverty (6).

With the International Classification of Functioning, Disability and Health (ICF) approved by the 54th World Health Assembly in 2001 (4), the WHO provides a universal and internationally accepted framework and classification (7). The ICF is a promising starting point for the integrative understanding of functioning, disability and health, and the overcoming of Cartesian dualism of body and mind as well as both sociological and biomedical reductionism (8). It is also a promising starting point for the development of rehabilitation practice and research (7,9).

The objective of this chapter is to introduce the reader to the ICF and how it relates to rehabilitation.

In the first section, we review the history and development of the ICF and describe its structure and validity. In the second section, we illustrate how to use the ICF for the classification and measurement of functioning. Finally, we discuss the current state of the implementation and application of the ICF with a focus on rehabilitation.

## THE ICF

### The ICF in the Historical Perspective

Clinicians have relied on classifications for the diagnosis of health conditions for over 100 years (10,11). The International Classification of Diseases (ICD) was first published as a classification of causes of death in 1898 (12). In the meantime,

the ICD is undergoing its 11th revision. The ICD was initially used for actuarial reasons to document death. It was later adopted for epidemiology and by public health to monitor health and interventions. Lately, it was used for clinical purposes, mainly driven by the need to classify diagnoses in the context of reimbursement systems including diagnostic-related groups.

By contrast, the first classification of disability, the International Classification of Impairment, Disabilities and Handicaps (ICIDH) (13) was published and released in 1980 for trial purposes only. The ICIDH and other models like the Institute of Medicine model (14,15), Nagi's model (16,17), and the Quebec model (18) have influenced the definitions of rehabilitation (9), the development of rehabilitation practice and research (9), and legislation and policy-making (7,15). The ICIDH model of disablement represented a real breakthrough in that disability was disentangled from disease by removing the disability section from ICD-8 and creating a separate classification.

Particularly in Europe, there was considerable interest in the application of the ICIDH as a unifying framework for classifying the consequences of disease during the last 20 years of the 20th century. For example, the Council of Europe launched its *Recommendation No. R (92) 6* on "a coherent policy for people with disabilities" based on the ICIDH (19). Other publications by the Council of Europe, for example, about the use and usefulness of the ICIDH for health professions (20) document this interest.

However, the ICIDH, which was never approved by the World Health Assembly as an official WHO classification, did not find worldwide acceptance (1,15). It was criticized by the disability community over time for the use of negative terminology, such as handicap, and for not explicitly recognizing the role of the environment in its model. In the reprint of the ICIDH in 1993, WHO thus expressed its intention to embark in the development of a successor classification.

### The ICF in the WHO and the UN Perspective

The endorsement of the ICF by the 54th World Health Assembly in May 2001 mirrors an important shift in the understanding of health and disability by the WHO. The ICF acknowledges that every human being can experience a decrement in health and thereby experience some disability. With the ICF, WHO responds to the need for a unified, international, and standardized language for describing and classifying health

and health-related domains. The ICF is WHO's framework for health and disability. It is the conceptual basis for the definition, measurement, and policy formulations for health and disability. The ICF thus complements the ICD that is used to classify deaths and diseases (11). To complement mortality or diagnostic data on morbidity and diseases is important since they alone do not adequately capture health outcomes of individuals and populations (e.g., diagnosis alone does not explain what patients can do, what their prognosis is, what they need, and at what treatment costs) (21,22).

As an international standard ICF contributes to various WHO's efforts related to the measurement of health and disability. For example, the ICF served as a framework for WHO's World Health Survey conducted in 70 countries (23,24). The WHA resolution 58.23 on "*Disability, including prevention, management and rehabilitation*" approved in May 2005 by the 58th World Health Assembly recalls the ICF framework (8). For the upcoming WHO World Report on Disability and Rehabilitation, the ICF provides the basis for the conceptualization of disability and reference framework for the disability statistics presented in the report. The International Society of Physical and Rehabilitation Medicine (ISPRM) which is the International Physical and Rehabilitation Medicine (PRM) organization in official relation with WHO, is represented on the advisory board of the report and is supporting the DAR team in this development.

While the ICF has been developed by WHO, the specialized agency responsible for health within the United Nations (UN) system, the ICF has been accepted as one of the UN social classifications (4). Therefore, the ICF has influenced the characterization of disability in the UN Convention on the Rights of Persons with Disabilities (25) approved on 13 December 2006 at the UN Headquarters in New York. While the convention does not establish new human rights, it does define the obligations on states to promote, protect, and ensure the rights of persons with disabilities. Most importantly, it sets out the many steps that states must take to create an enabling environment so that persons with disabilities can enjoy inclusion and equal participation in society. However, the ICF provides a more comprehensive approach defining disability than it is used in the UN Convention. Hence, there is the need for a common agreement on the meaning of disability (26).

### Development of the ICF

The ICF was developed by the WHO in a worldwide collaborative process involving the active participation of some 65 countries and a network of WHO Collaboration Centers for the Family of International Classifications (WHO-FIC). After three preliminary drafts and extensive international field testing, including linguistic and cultural applicability research, the successor classification which was first tentatively named ICIDH-2, the ICF was finalized in 2000 (4). So far, the ICF has been translated into 37 languages.

The ICF not only was derived from Western concepts but has worldwide cultural applicability. The ICF follows the principle of a universal as opposed to a minority model.

Accordingly, it covers the entire lifespan. It is integrative and not merely medical or social. Similarly, it addresses human functioning and not merely disability. It is multidimensional and interactive, and rejects the linear linkage between health condition and functioning. It is also etiologically neutral which means functioning is understood descriptively and not caused by diagnosis. It adopts the parity approach which does not recognize an inherent distinction or asymmetry between mental and physical functioning.

These principles address many of the criticisms of previous conceptual frameworks and integrate concepts established during the development of the Nagi model (16,17) and the Institute of Medicine model of 1991 (14,15). Most importantly, the inclusion of environmental and personal factors, together with the health condition, reflect the integration of the two main conceptual paradigms that had been used previously to understand and explain functioning and disability, that is, the medical model and the social model.

The medical model views disability as a problem of the person caused directly by the disease, trauma, or other health conditions and calls for individual medical care provided by health professionals. The treatment and management of disability aim at cure and target aspects intrinsic to the person, that is, the body and its capacities, in order to achieve individual adjustment and behavior change (27,28).

By contrast, the social model views disability as the result of social, cultural, and environmental barriers that permeate society. Thus, the management of disability requires social action, since it is the collective responsibility of society at large to make the environmental modifications necessary for the full participation of people with disabilities in all areas of social life (29–32). The ICF and its framework achieve a synthesis, thereby providing a coherent view of different perspectives of health (1).

### ICF Update and Future Developments

The ICF published in 2001 will—similar to the ICD—undergo updates and ultimately a revision process. The WHO coordinates the update process, in collaboration with the Network of the Collaboration Centers for the Family of International Classifications (WHO FIC CC Network).

Recognizing the importance of personal factors, which are included in the ICF conceptual model, the WHO is also exploring the possibility of developing a taxonomy of personal factors.

To meet the requirements of health and disability information systems in the 21st century, the digitalization of analogue information standards as used with the ICF is essential. This is why the work on an ICF Ontology (defining classification entities with their attributes and value sets) is regarded as a priority for future ICF development.

### The Structure of the ICF

As shown in Figure 11-1, the ICF is organized into two parts. Part 1 classifies functioning and disability formulated in two

**FIGURE 11-1.** The model of functioning and disability on which the ICF is based.

components: (a) body functions and structures and (b) activities and participation. Part 2 comprises the contextual factors which include the following two components: (a) Environmental factors and (b) Personal factors (currently not classified).

Definitions of some of the key terms used in ICF are given below.

Health condition is an umbrella term for disease (acute or chronic), disorder, injury, or trauma. A health condition may also include other circumstances such as pregnancy, ageing, stress, congenital anomaly, or genetic predisposition. Health conditions are coded using ICD-10.

Functioning is an umbrella term for body functions, body structures, activities, and participation. It denotes the positive aspects of the interaction between an individual (with a health condition) and that of an individual's contextual factors (environmental and personal factors).

Disability is an umbrella term for impairments, activity limitations, and participation restrictions. It denotes the negative aspects of the ICF that provides a detailed classification with definitions: body functions are the physiological functions of body

systems (including psychological functions); body structures are anatomical parts of the body such as organs, limbs, and their components; activity is the execution of a task or action by an individual; participation is involvement in a life situation; environmental factors make up the physical, social, and attitudinal environment in which people live and conduct their lives.

The component of body functions and structures refers to physiological functions and anatomic parts of the body system, respectively; loss or deviations from normal body functions and structures are referred to as impairments. The second component of activities and participation refers to a single list of life domains (from basic learning or walking to composite areas like interpersonal relationships or employment). The component can be used to denote activities or participation or both. "Activity limitations" are thus difficulties the individual may have in executing activities (7). "Participation restrictions" are thus problems the individual may experience with such involvement (7). The components of body functions and structures and activity and participation are related to and may interact with the health condition (e.g., disorder or disease) and contextual factors.

Contextual factors include the components of environmental factors and personal factors. Since in the current ICF, an individual's functioning and disability occurs in a context, ICF also includes a classification of environmental factors. The components of body functions and structures, activities and participation, and environmental factors are classified based on ICF categories. It is conceivable that a list of personal factors will be developed over the next years. The ICF contains a total of 1,495 meaningful and discrete or mutually exclusive categories. Taken together, the ICF categories are cumulative exhaustive and hence cover the whole spectrum of the human functioning. The categories are organized within a hierarchically nested structure with up to four different levels as shown in Figure 11-2. The ICF categories are denoted by unique alphanumeric codes with which it is possible to classify functioning and disability, both on the individual and population level.

**FIGURE 11-2.** The structure of the ICF and the distribution of the ICF's 1,424 categories across its four components and four levels of hierarchy.

**TABLE 11.1** Examples of ICF Categories with their Corresponding Code, Title, and Definition**Code<sup>a</sup> and Title, Definition, Inclusions and Exclusions**

b130	Energy and drive functions
General mental functions of physiological and psychological mechanisms that cause the individual to move towards satisfying specific needs and general goals in a persistent manner.	
<i>Inclusions: functions of energy level, motivation, appetite, craving (including craving for substances that can be abused), and impulse control</i>	
<i>Exclusions: consciousness functions (b110); temperament and personality functions (b126); sleep functions (b134); psychomotor functions (b147); emotional functions (b152).</i>	
b280	Sensation of pain
Sensation of unpleasant feeling indicating potential or actual damage to some body structure.	
<i>Inclusions: sensations of generalized or localized pain, in one or more body part, pain in a dermatome, stabbing pain, burning pain, dull pain, aching pain; impairments such as myalgia, analgesia and hyperalgesia.</i>	
s730	Structure of upper extremity
d450	Walking
Moving along a surface on foot, step by step, so that one foot is always on the ground, such as when strolling, sauntering, walking forwards, backwards, or sideways.	
<i>Inclusions: walking short or long distances; walking on different surfaces; walking around obstacles</i>	
<i>Exclusions: transferring oneself (d420); moving around (d455)</i>	
d920	Recreation and leisure
Engaging in any form of play, recreational or leisure activity, such as informal or organized play and sports, programmes of physical fitness, relaxation, amusement or diversion, going to art galleries, museums, cinemas or theatres; engaging in crafts or hobbies, reading for enjoyment, playing musical instruments; sightseeing, tourism, and travelling (lt. ICF) for pleasure.	
<i>Inclusions: play, sports, arts and culture, crafts, hobbies, and socializing</i>	
<i>Exclusions: riding animals for transportation (d480); remunerative and non-remunerative (lt. ICF) work (d850 and d855); religion and spirituality (d930); political life and citizenship (d950)</i>	
e1101	Drugs
Any natural or human-made object or substance gathered, processed or manufactured for medicinal purposes, such as allopathic and naturopathic medication.	

<sup>a</sup>The letter b refers to *body functions*, s: *body structures*, d: *activities and participation domains*, and e: *environmental factors*.

An example of the hierarchically nested structure is as follows: “b1 Mental functions” (first/chapter level); “b130 Energy and drive functions” (second level); and “b1301 Motivation” (third level). Based on the hierarchically nested structure of the ICF categories, a higher-level category shares the attributes of the lower-level categories to which it belongs. In our example, the use of a higher-level category (b1301 Motivation) automatically implies that the lower-level category is applicable (b130 Energy and drive functions).

Because the ICF categories are always accompanied by a short definition and inclusions and exclusions, the information on aspects of functioning can be reported unambiguously. Examples of ICF categories, with their definitions, inclusions, and exclusions are shown in Table 11-1.

## ICF-BASED CLASSIFICATION AND MEASUREMENT OF FUNCTIONING

### ICF Categories: Building Blocks and Reference Units

ICF categories with their definitions are the discrete, meaningful, and universally shared and understood entities, which allow

users to comprehensively classify functioning of individuals and populations.

Qualifiers allow us to indicate the functioning level in a particular category. In the case of the component of environmental factors, they show the degree of positive or negative impact of environmental factors on the individual's functioning. A most simple rule is binary coding. It assigns a “0” if a functioning problem is not present and “1” if it is present. A slightly more complex coding rule would be to assign a “0” if a functioning problem is not present, a “1” if it is somewhat present and “2” if a functioning problem is fully present. All three components classified in the ICF (body functions and structures, activities and participation, and environmental factors) are quantified using the same generic five-point scale. (“0” = no problem, “1” = mild problem, “2” = moderate problem, “3” = severe problem, “4” = complete problem). The qualifiers for the categories for the activities and participation component are capacity and performance. The qualifiers for the environmental factor categories are facilitators and barriers.

In general, coding based on specified rules is a form of measurement. According to Nunnally (33), measurement is the assignment of numbers to attributes, which represent particular features of an entity. In the specific case of the ICF, coding of the ICF qualifier, therefore, is a form of measurement since

it involves the assignment of numbers to attributes of ICF categories.

Beyond coding, it is possible to measure attributes based on a scaling model using a scale. An example is the use of a visual analogue scale (scale) based on a metric model (scaling model) for the measurement of intensity of pain (attribute) in relation to pain (ICF category b280). Another example is the use of a self-administered questionnaire (scale) based on a RASCH model (scaling model) for the measurement of a capacity limitation (attribute) in walking (ICF category d450). The advantage of using a scale over coding is the possibility to place a person or a so-called stimulus on a continuum as defined by a suitable scaling model. A RASCH-based scale allows us to place a person on a continuum in relation to the experience of other persons (the population). It also allows us to place, for example, a questionnaire item (a stimulus) on the continuum in relation to any other item (e.g., items included in item banks) representing this attribute of an ICF category.

Based on this understanding, it becomes clear that ICF categories serve as building blocks for both the classification and measurement of human functioning. It also becomes clear how ICF categories are distinct from measurement items. ICF categories represent meaningful and universally shared entities. Conversely, items are stimuli, which allow the quantification of attributes in relation to these entities. Different from the limited number of ICF categories constituting cumulative exhaustive entities of the human experience represented in the ICF, there are a virtually infinite number of measurement items conceivable.

Therefore, ICF categories are the building blocks for the construction of ICF-based tools such as the *ICF checklist* (34) and the *ICF Core Sets* (35–38) as well as *clinical measurement instruments* such as the *ICF Core Set Index* currently under development for Ankylosing Spondylitis (39) and *generic health status measurement instruments* such as the WHO Disability Assessment Schedule 2.0 (WHODAS 2.0) (40–43).

### ICF-Based Practical Tools: ICF Checklist, ICF Core Sets, and WHODAS 2.0

The ICF classification system contains 1,495 categories. “A clinician cannot easily take the main volume of the ICF and consistently apply it to his or her patients. In daily practice, clinicians will only need a fraction of the categories found in the ICF” (42). Therefore, “to be useful, ICF-based tools need to be tailored to the need of the prospective users without foregoing the information needed for health statistics and health reporting” (42). In response to this need, WHO and a wide range of partners including ISPRM have been collaborating in the development and promotion of ICF-based tools.

#### ICF Checklist

The ICF checklist provides a user-friendly display of the most relevant ICF categories and allows the user to identify and qualify the individual’s functioning profile in a simple but comprehensive and time efficient manner. The inclusion of diagnostic information in the checklist enables the user to study the

relationship between a health condition and the associated functioning problems. The listing of environmental codes and the possibility to record information on personal factors permits the user to document and understand the impact of contextual factors on the person’s functioning.

The ICF checklist has been applied in a wide range of surveys and in studies in the process of developing ICF Core Sets (Table 11-2). As a generic tool for recording and documenting an ICF-based functioning profile, the checklist has a proved utility and feasibility (44–46). In situations where more detailed functional status information is needed, the ICF checklist was found to be too generic and the need for more condition- or setting-specific ICF tools (e.g., ICF Core Sets) was noted (47,48).

#### ICF Core Sets

##### *The ICF Core Set Project*

The goal of the *ICF Core Set* project is to systematically develop parsimonious and hence practical sets of ICF categories for clinical practice, service provision, and research and to link the ICF to health conditions as coded with the ICD (35,38,42). The ICF Core Sets serve first as tools for the documentation of functioning and second as international reference standards for the reporting of functioning (7), irrespective of which measurement instruments were used. They are also the starting point for the development of clinical and self-reported measurement instruments (39,49,50).

The ICF Core Set Project is a joint project of the *ICF Research Branch* of the WHO FIC CC Germany (DIMDI) at the Institute of Health and Rehabilitation Sciences at the Ludwig-Maximilian-University in Munich, Germany (<http://www.ICF-research-branch.org>), together with WHO, ISPRM and a large number of partner organizations and associated institutions as well as committed clinicians and scientists (35,38,42).

#### Conceptual Approach

The conceptual approach for the development of the ICF Core Sets was derived from two perspectives: (a) the perspective of people who share the experience of the same condition (e.g., multiple sclerosis) or condition group (e.g., neurological conditions) and (b) the perspective of the health service context along the continuum of care and the life span.

##### *ICF Core Sets for the Acute Hospital and (Early) Post-acute Rehabilitation Facilities*

The *ICF Core Sets for the Acute Hospital* including the ICF Core Sets for neurological, cardiopulmonary, and musculoskeletal conditions are intended for use by physicians, nurses, therapists, and other health professionals not specialized in rehabilitation care provision (37,38). By contrast, the ICF Core Sets for *(early) post-acute rehabilitation facilities* including the ICF Core Sets for neurological, cardiopulmonary, and musculoskeletal conditions as well as the ICF Core Set for

geriatric patients are intended for use by physicians, nurses, therapists, and other health professionals specialized in rehabilitation or geriatric care provision (37,38). The use of the term early indicates the early part of rehabilitation where patients have both medical needs requiring hospital care and rehabilitation needs.

### *ICF Core Sets for Chronic Conditions*

The ICF Core Sets for chronic conditions are intended for use in the community-oriented (late) phase of rehabilitation and the community (35,36,42). For each chronic health condition, both a *Brief ICF Core Set* and a *Comprehensive ICF Core Set* have been developed. While the *ICF Core Sets* serve as tools for single encounters, minimum data sets for the reporting of clinical and epidemiological studies and health statistics, the *Comprehensive ICF Core Sets* are intended for use in multidisciplinary settings.

### *Generic ICF Core Set*

While the condition and context-oriented ICF Core Sets are useful when classifying functioning for patients with specific health problems in specific health care situations, a parsimonious set of categories is needed to be able to assess and compare functioning across conditions and contextual factors. The *Generic ICF Core Set* is currently being developed in an iterative process involving a number of criteria and methodological approaches. A first study in this process examined the explanatory power of determined ICF categories in relation to external standards across the 12 chronic conditions for which condition-specific ICF Core Sets had already been developed (51). The categories identified as candidate categories from this study are shown in Table 11-3.

### *Development Process*

While there are some singularities in the process of developing ICF Core Sets in relation to the context for which they are being developed, the development as illustrated in Figure 11-3 involves an international consensus process based on evidence gathered in a preparatory phase and an international testing

**TABLE 11.3** ICF Categories Identified as Candidate ICF Categories for the Generic ICF Core Set (51)

Body functions	b130 Energy and drive functions b152 Emotional functions b235 Vestibular functions b280 Sensation of pain b730 Muscle power functions
Activity and participation	d450 Walking d620 Acquisition of goods and services d640 Doing housework d660 Assisting others d850 Remunerative employment d920 Recreation and leisure
Environmental factors	e450 Individual attitudes of health professionals e580 Health services, systems and policies

and validation phase in the six WHO world regions (Africa, the Americas, the Eastern Mediterranean, Europe, South-East Asian, and the Western Pacific) (36).

The preparatory phase consists of (a) an empirical data collection based on the ICF, reflecting the perspective and the condition of the patient, (b) an expert survey using the Delphi method, (c) a systematic review on outcomes used in observational and experimental clinical studies, which also represents the view of experts, and (d) additionally, for ICF Core Sets now in the preparatory phase, a qualitative study using focus groups or patient interviews, representing the view of patients complement the methods. The results of the preparatory studies are presented at a consensus conference. They represent the starting point for a structured decision-making and consensus process in which clinicians and health professionals, experts in the field for which the specific ICF Core Set is to be developed, participate. Finally, the ICF Core Sets are tested and validated in an international effort in a wide range of contexts.

**FIGURE 11-3.** Illustration of the process to develop ICF Core Sets.

In these contexts, three different approaches are used to ensure and examine the validity of the ICF Core Sets. In the first approach, patient focus groups determine whether from the perspective of patients all aspects of functioning are covered by the ICF Core Sets (52). In a second approach, the Delphi technique is used to identify the intervention goals that are relevant for health professionals treating patients. In a subsequent analysis it is examined how these intervention goals are represented by the current version of the Comprehensive ICF Core Sets (53,54). In a third approach, the ICF Core Sets are applied to patients in different settings to gather information about the relevance of the categories. The preliminary results from the patients' and health professionals' perspective, support the validity of the ICF Core Sets. However, some categories currently not covered by the ICF Core Sets should be considered for inclusion in an updated version of the ICF (52–54).

### WHO Disability Assessment Schedule (WHODAS 2.0)

For the standardized cross-cultural measurement of health status, the WHO has developed an ICF-based assessment instrument, the WHODAS 2.0. The WHODAS 2.0 is chosen from a comprehensive set of ICF items that are reliable and sensitive enough to measure what difference a given treatment makes: assessing the same individual before and after an intervention. It has been designed to assess the activity limitations and participation restrictions experienced by an individual irrespective of medical diagnosis. The primary version of WHODAS 2.0 is a fully structured 36-item lay interviewer-administered assessment instrument. It queries difficulties in six domains of life during the last 30 days. For all six domains, the WHODAS 2.0 provides different profiles and a single summary score. The following domains were selected after a careful review of existing research and survey instruments and the cross-cultural applicability study (55):

Understanding and communicating with the world (cognition); moving and getting around (mobility); self-care (attending to one's hygiene, dressing, eating, and staying alone); getting along with people (interpersonal interactions); life activities (domestic responsibilities, leisure, and work); participation in society (joining in community activities).

The WHODAS 2.0 has been shown to be useful for assessing health and disability levels in the general population through surveys; and it is an aid for measuring the clinical effectiveness of interventions and productivity gains as a result of treatments (24,56–63). The psychometric properties of WHODAS 2.0 show good to very good internal consistency ( $\alpha = 0.86$ ), a stable factor structure, a high test-retest reliability ( $ICC=0.98$ ), concurrent validity, conforms to RASCH scaling properties across populations and is sensitive to change (effect size = 0.44–1.38) in different populations (64–67). A study applying the WHODAS 2.0 in rehabilitation using a German version found that it is a useful instrument for measuring functioning and disability in patients with musculoskeletal diseases, internal diseases, stroke, breast cancer, and depressive disorder (68). However, for the domain *household and work activities*, a clear

distinction between *work activities* versus *household activities* was apparent in musculoskeletal and internal conditions (68). Therefore, a separate scoring of the WHODAS 2.0 with and without the items on remunerated work is provided (54).

The WHODAS 2.0 has been translated into over 20 languages and comes in several versions: A 36-item, 12-item version and an adaptive 12+24 item version. All three versions are available in interviewer-, self-, and proxy-administered format. The average time to complete the questionnaire for the 12-item version is approximately 5 minutes and for the 36-item version, 20 minutes.

### Mapping the World of Measures to the ICF Applications

Since the ICF is the universal and standardized language to describe and report functioning and health, users need to be able to map the world of measures to the ICF. The *mapping of concepts (qualitative mapping)* of measurement instruments to the ICF relies on *linkage rules* (69,70). The *quantitative mapping* relies on transformations using the RASCH model (41).

*Mapping of concepts* is applied for the content comparison of measurement instruments, for example, when studying their comparative content validity. The ICF-based comparison of measurement instruments can, therefore, assist researchers and clinicians to identify and select a most suited measurement instrument for a specified purpose. ICF-based comparisons also enable researchers to ensure that all ICF categories of a suitable ICF Core Set are covered by candidate measurement instruments and hence to report functioning according to standards (7) as described in the last section of this chapter. Table 11-4 lists studies which have compared the most widely used measurement instruments for specified health conditions as well as a comparison of generic health status measures.

*Mapping of concepts, in combination with quantitative mapping*, is used for the identification of items addressing the construct covered by a specified ICF category and the construction of RASCH scales to estimate the level of functioning for this category. As we will describe in more detail in the following paragraph, this involves the identification of items from measurement instruments that address the construct of a specified ICF category within their scope. Another example of qualitative combined with quantitative mapping is the transformation of information from electronic records (71).

### Linkage Methodology

The linking methodology allows users to map contents from measurement instruments to the ICF and vice versa. The first step refers to the identification of concepts within the health-related information to be translated to the ICF. The second step refers to linking those concepts to the ICF.

#### Step One: Identification of Key Concepts

The first step, the identification of key concepts, varies slightly depending on the origin of the information that is to be

translated. In health-status questionnaires, the concepts refer to the different contents addressed in each of its items. A single item may contain more than one concept. For example, item 8 of the SF-36 “During the past 4 weeks, how much did pain interfere with your normal work (including both work outside the home and housework)” contains three different concepts “pain,” “work outside the home,” and “housework” (69). It is also possible to identify concepts from qualitative data such as interviews (Table 11-5), clinical assessments, and clinical interventions.

### ***Step Two: Linking of Concepts to the ICF***

After the key concepts have been identified, the second step involves the linking of those concepts to the ICF according to

ten rules. An example of the linkage of concepts to the ICF is shown in Table 11-5.

Both steps of the linking methodology should always be performed by two trained health professionals independently of each other. Thus, after the second step, two independent results of the linking process exist. These results are compared. The reliability of the linking process is evaluated by calculating kappa coefficients (72) and nonparametric bootstrapped confidence intervals (73,74) based on the two independent linking results in order to indicate the degree of agreement between the two health professionals. Well-trained health professionals showed a considerable degree of agreement (69) when linking health-status measures to the ICF.

## Principles of ICF-Based Measurement of Functioning

### Measuring a Single ICF Category

In principle, there are two approaches to measure a specified ICF category, that is, to quantify the extent of variation therein. The first is to use the *ICF qualifier* as a rating scale ranging from 0 to 4 (Table 11-6). The second is to use information obtained with a clinical test or a patient-oriented instrument and to transform this information into the ICF qualifier.

### Direct Coding of the ICF Qualifier

With this approach, a physician or health professional integrates all accessible and suitable information from the patient's history, clinical, and technical exams to *code* a specified category according to established coding guidelines (75). To ensure quality in a specific setting, it is advisable to regularly assess the reliability of coding (76). Figure 11-4 shows a simple and informative graphical approach to assess the interobserver reliability of *ICF qualifier codes* (76). The rating of certain ICF categories may be facilitated by complementary instructions provided, in addition to the descriptions of the ICF categories as provided in the ICF reference material. Table 11-7 shows an additional instruction developed by the American Psychological Association (2007) (77) for the ICF category *b130 Energy and drive functions* for which the original description in the ICF reference material is given in Table 11-6. Similar instructions have been developed by the American Psychological Association for a large number of ICF categories (77).

### Transformation of Information Obtained with a Clinical Test or a Patient-Oriented Instrument

With the second approach, the ICF qualifier serves as a reference scale. The results from a clinical test or a patient-oriented measurement instrument are transformed into the ICF qualifier.

For many ICF categories there are suitable *clinical tests* which include standardized expert and technical examinations or *patient-oriented measurement instruments* which include patient and proxy-reported, self-administered, or

**FIGURE 11-4.** Bangdiwala observer agreement chart for ICF-category d430. The chart is a *square* whose edges are determined by sample size. The edges of the *black squares* show the number of patients who got identical ratings from both observers. The large bright *rectangle* shows the maximum possible agreement, given the marginal totals. Partial agreement is showed by including a weighted contribution from off-diagonal cells, here represented by hatching. One observer's ratings would differ systematically from the other observer's ratings if all *black squares* were above or below the diagonal.

interviewer-administered questionnaires which are routinely used in clinical practice or for research purposes. In this case, information already available can be transformed to report the results in the standard language of the ICF.

Since the ICF qualifier is a rating scale for which WHO has provided percentage values as a reference (Table 11-6), transformation to the ICF qualifier is straightforward in the case of interval-scaled clinical tests or patient-oriented instruments, which comprehensively and uniquely cover the content of a respective ICF category. For example, the visual analog scale (VAS) to assess pain can be used to address the ICF category *b280 Sensation of pain*. The values of VAS-Pain can be transformed into an ICF qualifier in a straightforward manner, since it represents a 100 mm interval scale marked as “no pain” at one end and as “worst pain” at the other (78). Considering the percentage values of the ICF qualifier in Table 11-6, a person marking a level of pain between 0 (zero) and 4 mm would receive the qualifier 0 in the ICF category *b280 Sensation of pain* between 5 and 24 mm the qualifier 1, between 25 and 49 mm the qualifier 2, between 50 and 95 mm the qualifier 3, and between 96 and 100 mm the qualifier 4.

In the case where there are no readily available clinical tests or patient-oriented instruments with interval-scale properties that can be used to assess a specified ICF category one may consider the construction of an *ICF category interval scale* using parts of clinical test batteries or selected items of patient-oriented measurement instruments that cover a specified ICF

**TABLE 11.6** ICF Qualifier With Percentage Values Provided by the WHO

ICF Qualifier <sup>a</sup>	Percentage of Problem (%)
0 No problem (none, absent, negligible,...)	0–4
1 Mild problem (slight, low,...)	5–24
2 Moderate problem (medium, fair,...)	25–49
3 Severe problem (high, extreme,...)	50–95
4 Complete problem (total,...)	96–100

<sup>a</sup>“Having a problem may mean an impairment, a limitation, a restriction or a barrier, depending on the construct,” that is, depending on whether we are classifying body functions and structures (impairments), activity and participation (limitations or restrictions), or environmental factors (barriers or facilitators).

**TABLE 11.7** Additional Instructions for ICF Categories Illustrated with the Example *b130 Energy and Drive Functions***b130: Energy and drive functions**

General mental functions of physiological and psychological mechanisms that cause the individual to move towards satisfying specific needs and general goals in a persistent manner.

Inclusions: functions of energy level, motivation, appetite, craving (including craving for substances that can be abused), and impulse control

Exclusions: consciousness functions (b110); temperament and personality functions (b126); sleep functions (b134); psychomotor functions (b147); emotional functions (b152)

**Additional information**

This code includes general behavioral tendencies including *Energy level b1300* and *Motivation b1301* to move toward goals. It also includes the constructs of *Appetite b1302* and *Craving b1303*, which may be general tendencies or relate to specific substances or behaviors (e.g., psychoactive substances, food, gambling). In addition, this code includes *Impulse control b1304*, which may refer to impulses in general or relate to more specific impulses to engage in particular behaviors. This code and its subcodes should be used only to refer to characteristics or behaviors that are consistent or occur frequently over time, not to single behaviors or transitory states.

These codes may be useful in a variety of settings. Motivation, craving, and impulse control are often a part of motivational assessment in relation to substance abuse treatment or other treatments that have the goal of reducing, avoiding, or abstaining from particular behaviors (e.g., substance use, overeating, gambling). In such cases, impairments related to these factors may be a part of the disorder. Energy level and motivation may also be important in cases of CNS injury or disease (e.g., stroke), where concerns related to “lack of initiation” or “mental fatigue” may be present, and in patients with psychological disorders such as depression and bipolar disorder. Impairments in impulse control are, by definition, a part of substance abuse and impulse-control disorders, and may also be a central part of a variety of other psychological disorders including attention deficit hyperactivity disorder, conduct disorder, and bipolar disorder.

Generally, *Energy level b1300* and *Motivation b1301* should be reserved for cases in which abnormal levels or significant changes in energy level and motivation occur as a direct result of a disorder, disease process, or injury, or as an effect of treatment (e.g., decreased energy level is a side effect of some medications).

Motivation is considered to be particularly important in relation to the success of treatment for many health conditions. However, caution should be exercised in assigning this code. Body functions are meant to be coded with the ICF to the extent that impairments are attributable to a health condition or health-related state, which will not be to the extent that high or low motivation is a general personality characteristic of the individual. This is not to say that it will not be highly relevant to treatment, only that it would correspond more closely in this case to what the ICF identifies as *Personal Factors* rather than to *Body Functions*. In addition, *Motivation b1301* should not be used to describe an individual’s motivation to comply with a specific treatment, such as physical therapy in rehabilitation programs. Finally, lack of motivation may be used by health care personnel or others in the patient’s social environment as a pejorative explanation for a patient’s lack of progress in treatment, one that attributes the problem to the patient. It is important not to attribute lack of motivation to patients who are physically or mentally unable to perform particular tasks or actions, or who are not receiving the most appropriate treatments to help them progress.

**Case Examples**

Following a stroke, a 67-year-old woman has difficulty selecting or getting started on projects, and often complains of feeling “too tired” and “mentally worn out.”

A 45-year-old man with an alcohol abuse disorder refuses all attempts at treatment, indicating that although he recognizes the negative consequences of substance use in his life, he is not willing to stop drinking.

**Other codes within this section**

- b1300: Energy level
- b1301: Motivation
- b1302: Appetite
- b1303: Craving
- b1304: Impulse control
- b1308: Energy and drive functions, other specified
- b1309: Energy and drive functions, unspecified

category. Figure 11-5 illustrates the construction of an interval reference scale using the RASCH model to estimate the level of functioning for *b130 Energy and drive functions* (41). Sixteen of the 19 items linked from three instruments did fit the RASCH model and could be integrated in an ICF cat-

egory interval scale. Based on this principle, clinicians can estimate the level of *b130 Energy and drive functions* by adding the responses to the 16 items. In clinical practice, one would obviously need only a subset of possibly five items to reliably estimate the level of functioning in *b130 Energy and drive*

**FIGURE 11-5.** RASCH scale for measurement items mapped to the ICF category b130 energy and drive. The x- and y-axes represent the ICF category interval scale of the continuum *energy and drive*, with values ranging from 0 to 100. Not all values from 0 to 100 are represented on the y-axis because of space constraints. The 16 items in order of difficulty from the easiest item (**bottom**) to the most difficult item (**top**) are presented on the y-axis. The value corresponding to the position of the items is presented next to them. The position of the thresholds of the response options of the items are represented by the *bars* in the diagram. The different *gray tones* represent the different response options for each individual item. The *vertical arrows* represent the position of each of the response options of the ICF qualifier. Rheumatoid Arthritis Quality of Life Questionnaire (RAQoL), the Health Assessment Questionnaire (HAQ), the Medical Outcomes Study Short Form 36 (SF-36), the European Quality of Life Instrument (EQ-5D), the Multidimensional Fatigue Inventory (MFI), and the Center for Epidemiological Studies Depression Scale (CES-D).

*functions*. Alternatively, one may increase efficiency by using computer adaptive testing (CAT). Whatever method is used, the obtained raw scores can then be transformed into the ICF qualifier which serves as a reference scale.

A major advantage of the second approach is that the original format of the items used to construct the *ICF category interval scale* remains unchanged. Thus, it is possible to use the information provided by items within the context of their original instruments and, at the same time, within the context of the ICF. This application can be extremely useful, given the increasing use of the ICF and the ICF qualifier as references when documenting and reporting functioning and disability (79,80).

### Measuring Across ICF Categories ICF-based Measurement

The WHODAS 2.0 provides a generic measure of health status and disability as described in the previous section (56,68).

For specific conditions and/or settings, one may want to use a specific measurement instrument. A suitable starting point for the development for such measurement instruments are the ICF Core Sets. The ICF Research Branch of the WHO FIC CC Germany at the University of Munich is thus cooperating with and supporting research groups in the process to develop self-reported questionnaires based on the *ICF Core Sets* ([www.icf-research-branch.org](http://www.icf-research-branch.org)).

Clinician's ratings of the ICF Qualifier (Table 11-6) across a number of ICF categories, for example, across the categories of an ICF Core Set, can be reported in the form of a categorical profile. A categorical profile across a valid set of ICF categories such as an *ICF Core Set* provides an estimation of a person's *functioning state*. The *functioning state* is the central information for clinicians when planning and reporting the results of a health care intervention. Table 11-8 shows the example of *functioning states* at the start and the end of a rehabilitation program.

**TABLE 11.8 ICF-based Assessment and Evaluation Including Goal Setting and Goal Achievement in a Patient After Spinal Cord Injury. The Functioning States at the Start of Rehabilitation and After 4 Weeks are Shown as Categorical Profiles Based on Expert Ratings of the ICF Qualifier**

Assessment (12 weeks posttrauma)					Evaluation (16 weeks posttrauma)

Influence of Environmental Factors on Functioning		Facilitator					Facilitator				
		4+	3+	2+	1+		0	1	2	3	
e1101	Drugs	<div></div>				2+	<div></div>				✓
e1151	Assistive product: chair cushion	<div></div>				0	<div></div>				✓
e1201	Assistive product mobility: wheelchair, car	<div></div>				0	<div></div>				✓
e155	Design and construction of private building	<div></div>				2	<div></div>				✓
e5700	Social security services	<div></div>				4+	<div></div>				—
e5750	General social support services	<div></div>				3+	<div></div>				—
Influence of Personal Factors on Functioning		Positive		Neutral	Negative		Positive		Neutral	Negative	
		+		0	–	+		0	–		
pf	Knowledge of disease					+					✓
pf	Acceptance of disease					0					✓✓

<sup>a</sup>ICF Qualifier range from 0 = no problem to 4 = complete problem in the components of body functions (b), body structures (s), activities and participation (d) and from –4 = complete barrier to +4 = complete facilitator in the environmental factors. In personal factors, the sign + and – indicates to what extent a determined personal factor has a positive or negative influence on the individual's functioning.

The aggregation of information obtained from a *categorical profile* using the RASCH model results in a summary score (39,50). In the case of aggregation of information across a valid set of categories such as an *ICF Core Set*, the summary score provides an estimation of a person's *functioning status*. If using an electronic clinical chart, the creation of a score from a categorical profile created based on an ICF Core Set does not require additional work. *Functioning status* information provides clinicians with an intuitive, overall understanding of a patient's general level of functioning. It can be used by clinicians, service program providers, and payers, for example, for the assignment of patients to suitable rehabilitation service programs, to monitor and manage person's functioning along the continuum of care and across service program providers, to evaluate service programs, to predict resources and hence costs, and to derive payment schemes.

The principle of how to develop one- or multidimensional *Clinical Measurement Instruments* based on clinicians ratings of *ICF Core Sets* has been recently demonstrated (39,50). It could also be demonstrated how to apply such scores across countries by adjusting for differential item function. It is thus possible to compare functioning status information across countries and world regions.

### Validity of the ICF

A wide range of studies across world regions and user perspectives have been examined and have provided empirical and theoretical evidence supporting different aspects of the validity of the ICF framework. They include exhaustiveness, or width, and precision, or depth, of the classification.

#### Exhaustiveness or Width

A classification needs to be exhaustive by its very nature. In relation to the ICF and its categories, exhaustiveness refers to the coverage of the complete spectrum of health and health-related domains that make up the human experience of functioning and disability, and the complete spectrum of environmental factors that influence that experience of functioning and disability. Exhaustiveness is thus closely related to the concept of width, which refers to the number of distinct health and health-related domains at the same level of specification included in the classification. Based on results of published studies, the ICF appears to fulfil the formal criteria of exhaustiveness, especially in relation to the bandwidth of covered domains. In this respect, the results of the studies conducted in the context of the *ICF Core Set* development (35–37) (Table 11-2) can be considered “proof of concept.”

The ICF has been shown to be a highly comprehensive classification covering virtually all aspects of the patient experience. More specifically, the ICF has covered the spectrum of problems encountered in people with a wide range of conditions and along the continuum of care. Ongoing validation studies for the ICF Core Sets from the patient and health professional perspectives (Table 11-2) have shown that the ICF broadly covers patient problems and aspects of functioning treated by occupational therapists (53), physiotherapists (54), and

psychologists (53), for example, in patients with rheumatoid arthritis. The results also show that health professionals from different professions differ greatly in their intervention goals, reflecting the importance of validating the ICF from the perspective of many different health professions.

Further proof as to the comprehensiveness of the ICF is the finding that items of a wide range of measurement instruments (Table 11-4) can be mapped to the ICF. Most importantly, the ICF broadly represents the contents of health-related quality of life measures (81).

#### Precision or Depth

The second consideration for a classification is its depth, or precision. Depth, or precision, can be defined as the number of distinct levels of specification differentiated within a health or health-related domain. Most importantly, the level of specification of ICF categories was established in relation to the human experience of people across a wide range of health conditions, along the continuum of care, along the life span and across the WHO regions. Since the ICF categories are intended to be discrete and meaningful entities, they reflect the intuitive level or the level of informed “lay experts” but not the level of “professional experts” in a specific area.

Few studies have so far explicitly addressed this issue. A study that linked health-related quality of life measures to the ICF found that items with different content are linked to the same ICF category (82). This can be seen as an indication that the ICF does not differentiate these categories adequately. One example is the category b152, Emotional functions. In a review of the items of the SF-36 and the Nottingham Health Profile, different items of these instruments were linked to the same ICF category b152, even though they referred to different emotions. Based on this and other results, the most common emotional functions that could be specified in a future version of the ICF are: sadness, happiness, anxiety, and anger (82).

#### ICF Framework

Jette has rightly argued that for “scientific investigation, a crucial aspect of any conceptual framework is its internal coherence and its ability to differentiate among concepts and categories within the framework (83). Without empirical differentiation, conceptual frameworks cannot be investigated and validated. One of the common criticisms of the original ICIDH was that it was difficult to ascertain the boundaries between the basic concepts; each lacked the clarity and distinctness necessary for useful empirical testing (84–88). Thus, for the ICF to be useful as a framework for research, it is critical that the classification be clear about the phenomena it classifies with distinct and measurable definitions of each component. Without distinct and measurable dimensions, researchers will have trouble using the ICF for hypothesis development, study design and measurement construction” (89).

An important question with regard to the components of the ICF framework is the differentiation of activities and participation (90,91), and, the relationship with capacity and performance. The activities and participation component consists of a single list of functioning domains indicating actions

and life areas. In annex 3 of the ICF, four alternative options for structuring the relationship between activities and participation in terms of the domain list are given. The main options described in annex 3 of the ICF are (a) Distinct sets of activities domains and participation domains (no overlap); (b) Partial overlap between sets of activities and participation domains; (c) Detailed categories as activities and broad categories as participation, with or without overlap; (d) Use of the same domains for both activities and participation with total overlap of domains. In option (d) all categories can, however, be rated in terms of capacity and performance.

In the ICF publication, the WHO thus noted that “with the continued use of ICF and the generation of empirical data, evidence will become available as to which of the above options are preferred by different users of the classification. Empirical research will also lead to a clearer operationalization of the notions of activities and participation” (4). The respective results from current studies analyzing the differentiation between activities and participation are inconclusive (89,92). In addition, a recent review on the ICF concluded that there is little consensus regarding the distinction between activities and participation (93). However, the insights gained from these studies can contribute to the further development of the ICF.

Another approach to study the validity of the ICF framework is its reflection from the perspective of theoretical or professional models in relation to functioning. For example, occupational therapy models which focus on occupations and activities of daily living in the context of the environment can be expected to be closely related to the ICF. In a paper exploring the link of conceptual occupational therapy models to the ICF, the majority of the concepts from three conceptual occupational therapy models could be linked to the ICF (53,94,95). The ICF also proved to be useful as a framework for comparing the similarities and differences of the three conceptual occupational therapy models. The findings of the study also demonstrated that there are strong conceptual connections between the ICF and occupational therapy models, which encourage occupational therapists to use the ICF in their practice (94).

## IMPLEMENTATION AND APPLICATION OF THE ICF

### Official Implementation

With the approval of the ICF, the WHO member states are called upon to implement the ICF in the health, education, labor, and social sector. The implementation of the ICF is coordinated by WHO, in collaboration with the WHO FIC CC Network in which members of WHO and members of WHO Collaborating Centers from all WHO world regions are represented. An ongoing effort is to promote the use of the ICF and improve international comparability of functioning and disability data by establishing standardized procedures and implementation guidelines for different applications of the ICF. Examples of current implementations include the use of the ICF in health

and disability surveys, clinical services, disability certification, services use, and education. Especially in the field of rehabilitation, the ICF is exemplary implemented for the rehabilitation management in rehabilitation facilities (96). The ICF and the WHODAS 2.0 have been used in multiple health and disability surveys at global, regional, and national levels (23,24,97–100).

### Implementation and Applications in the Health Sciences

Parallel to the official implementation activities, the ICF has found immediate interest in the health sciences and particularly rehabilitation (7,43). By 2008 there have been over 600 ICF-related publications reflecting the interest, relevance, and impact of its application in health and particularly rehabilitation research worldwide.

The ICF itself has become the focus of interest of scholars worldwide. It has been critically discussed in a number of papers in recent reports by the Institute of Medicine on the future of disability in America (90,91). ICF-related applications include the use of ICF for the classification and measurement of functioning, as presented in the previous section. In the next paragraph, we discuss applications of specific relevance for rehabilitation. In this context it is important to recall that the ICF is relevant not only to PRM but also to allied professional groups, including physiotherapy, occupational therapy, psychology, and social work. In physiotherapy and occupational therapy, many curricula are now already based on or have integrated the ICF (101). Also, following reports on the application of the ICF in rehabilitation (43,102–104), there are now also reports on the application of the ICF in other medical specialties in which rehabilitation is a major health strategy (19) including psychiatry (105–107) and rheumatology (103). OMERACT, an international group committed to the standardization of outcome measures in rheumatology now uses the ICF as their reference framework (108,109).

### The ICF, a Unifying Framework for the Conceptualization of Rehabilitation

Rehabilitation is the public health strategy which focuses on functioning and complements the preventive, curative, and supportive strategy (19). The ICF, therefore, is the relevant framework and universally applicable taxonomy for conceptual descriptions and definitions of rehabilitation (19). Initiated by the Journal of Rehabilitation Medicine, the official Journal of ISPRM, a process towards universally agreed conceptual descriptions of rehabilitation and the rehabilitation professions has been started in 2007. A brief version of the current conceptual description as shown in Table 11-9 describes rehabilitation as the “health strategy applied by PRM and professionals in the health sector and across other sectors which aims to enable people with *health conditions* experiencing or likely to experience *disability* to achieve and maintain optimal *functioning* in interaction with the *environment*” (19). A brief version of the conceptual description for PRM as shown in Table 11-10 describes our field as “the medical specialty that based on the assessment of *functioning* and including the

**TABLE 11.9** Conceptual Description of the Rehabilitation Strategy (19). ICF Terms in the Proposed ICF-Based Conceptual Description are Marked in Bold.

Rehabilitation is the health strategy that is based on WHO's **integrative model** of **human functioning and disability** and applies and integrates biomedical and engineering approaches to optimize a **person's capacity** approaches that build on and strengthen the resources of the person approaches that provide a **facilitating environment** approaches that develop a **person's performance** in the interaction with the **environment** over the course of a **health condition** along and across the continuum of care ranging from the acute hospital and rehabilitation facilities to the community and across sectors including health, education, labor and social affairs with the goal to enable people with **health conditions** **experiencing** or likely to experience **disability** to achieve and maintain optimal **functioning** in interaction with the **environment**

Rehabilitation is the core strategy of the medical specialty PRIM, a major strategy of the rehabilitation professions, a relevant strategy of other medical specialties and health professions as well as service providers and payers in the health sector, and a relevant strategy of professionals and service providers across sectors caring for or interacting with people with **health conditions** experiencing or likely to experience **disability**.

diagnosis and treatment of *health conditions* performs, applies and coordinates biomedical and engineering and a wide range of other interventions with the goal of optimizing *functioning* of people experiencing or likely to experience *disability*" (79).

### The ICF, a Unifying Framework for the Development of Human Functioning and Rehabilitation Research

Until recently, a main barrier to the development of human functioning and rehabilitation research was the lack of a globally agreed framework and classification of human functioning, disability, and health (9). This unfortunate situation has changed with the approval of the ICF by the 54th World Health Assembly in 2001 (4). The universally applicable and integrative model of human functioning and disability is suited to serve as a unifying framework not only for the conceptualization of rehabilitation described in the previous paragraph (19,79) but also for the organization and development of *human functioning and rehabilitation research* as a research area ranging from the *cell to society* (9). Figure 11-6 shows a graphical depiction and short description of a proposal to organize *human functioning and rehabilitation research* into five distinct scientific fields (110) based on the ICF framework.

### The ICF, the Basis for Rehabilitation Management

The ICF has the potential to importantly contribute to the quality of rehabilitation care delivery. It can serve as a starting point to structure clinical assessment and rehabilitation management (7,103,111,112) which generally involves the four steps *assessment*, *assignment*, *intervention*, and *evaluation* (43). Respective training materials are provided on the internet by Swiss Paraplegic Research which uses the example of spinal cord injury (<http://www.icf-casestudies.org>).

In the context of a *case management situation*, the assessment step includes the identification of patients' problems and the definition of *long-term goals* and the *service program goals* of an envisioned rehabilitation program that is specified in the assignment step. The evaluation step refers to the evaluation of *service program goal* achievement.

In the context of a *rehabilitation service program*, the *assessment* step includes the identification of *patients' problems*, the review and potential modification of the assigned *service program goal*, and the definition and modelling of the first *cycle goals* and *intervention targets*. Patients' problems can be assessed in a non-systematic or in a systematic way using the applicable *ICF Core Sets*. To use a systematic approach using an *ICF Core Set* either alone or in addition to the nonsystematic approach is advisable to ensure that all potentially relevant problems have been addressed. The systematic approach is particularly useful in the training situation of team members. The structured approach also has the advantage that different team members can take primary responsibility for defined categories.

The *assignment* step refers to the assignment to health professionals and intervention principles. The *intervention* step refers to the specification of the intervention techniques, indicator measures, and target values to be achieved in a predefined time period and the monitoring of the intervention. The *evaluation* step refers to the evaluation of goal achievement with respect to the specified cycle goals and intervention targets.

The ICF framework is useful in all steps and can, for example, in the assessment step be used as a structure for an *ICF sheet*, with an upper section for the patient perspective and a lower section for the professional perspective as illustrated with an example in Figure 11-7 (102,103). This is a practical way to structure and document patient's problems and clinical and technical examinations. Also, important personal and environmental factors can be denoted.

The use of the ICF may enhance a structured approach to rehabilitation management and ease the communication of the team with respect to problems, goals, intervention categories, and interventions. Most importantly, it may improve the communication between settings, with insurers or case managers. An ICF-based rehabilitation management approach is also most useful in the context of clinical quality management and assurance, research and evidence-based rehabilitation, training and best practice, and in the formulation, implementation, and evaluation of guidelines. In the context of disability evaluation, the ICF provides a comprehensive framework for assessment and modelling of the determinants of work incapacity.

**TABLE 11.10 Conceptual Description of PRM (79). ICF Terms in the Proposed Description are Marked in Bold.**

*PRM is the medical specialty, which, based on:*  
the World Health Organization's (WHO) integrative model of human **functioning** and rehabilitation as its core health strategy,  
applies and integrates the biomedical and engineering approach to optimize a person's **capacity** with approaches which build on and strengthen the **resources** of the **person**, provide a **facilitating environment** and develop **performance** in the interaction with the **environment**,  
involves the diagnosis and treatment of health conditions,  
assesses **functioning** in relation to **health conditions**, personal and environmental factors including prognosis; the potential to change the prognosis; identification of long-term goals, intervention program goals, rehabilitation-cycle goals and intervention targets; and the evaluation of disability  
performs or applies biomedical and engineering interventions to optimize **capacity** including physical diagnostics, e.g. electro-neurophysiologic testing, assessment of endurance, force and co-ordination; physical modalities such as mechano-therapy including massage, exercise, strengthening and mobilization techniques, heat and cold, water and balneology, light and climate, electric currents including functional electro-physiologic stimulation; neuropsychological interventions; acupuncture, nerve root blockades and local infiltrations; nutritional and pharmacological interventions; rehabilitation technology including, for example, implants, prostheses and orthoses, aids and devices  
*suitable to*  
stabilize, improve or restore **impaired body functions and structures** including e.g. deconditioning; incontinence; sleep and swallowing disturbance; joint instability; and the minimization of pain, fatigue and other symptoms,  
prevent **impairments**, medical complications and risks including, for example, depression, sleep disturbance, skin ulcers, thrombosis, joint contractures and muscle atrophy, osteoporosis and falls,  
compensate for the absence or loss of **body functions and structures** including, for example, amputation; vision and hearing impairments  
leads and coordinates intervention programs to optimize performance  
in a multi-disciplinary iterative problem-solving process  
performing, applying and integrating  
biomedical and engineering interventions; psychological and behavioral; educational and counseling; occupational and vocational; social and supportive; and physical environmental interventions  
provides advice to patients and relevant persons in their immediate **environment**, service providers and payers  
over the course of a **health condition**  
along and across the continuum of care ranging from the acute hospital to rehabilitation facilities and the community  
and across sectors including health, education, labor and social affairs  
manages rehabilitation, health and multisectorial services  
informs and advises the public and decision-makers about suitable policies and programs in the health sector and across the other sectors which:  
provide a **facilitating** larger **physical and social environment**;  
ensure access to rehabilitation services as a human right;  
and empower PRM specialists to provide timely and effective care  
*with the goal*  
to enable people experiencing or likely to experience **disability** to achieve and maintain optimal **functioning** in interaction with the **environment**

### ICF-Based Standards for the Planning and Reporting of Studies

Currently, rehabilitation studies are often difficult to interpret for the reader. A main reason is the widely varying taxonomy due to a lack of a generally accepted framework and taxonomy for functioning, disability, and health before 2001. Authors who all have the same construct in mind referred to and still refer to "function," "physical function," "physical functional disability," "physical disability," "disability," "functional limitation," or "quality of life." The reader is thus often left wondering what the study is all about. Readers may also find that primary and secondary study endpoints are not explicitly denoted.

The endpoint may be defined in terms of a measurement instrument totally unknown to the reader when there is a wide variety of them in use. And because measurement instruments typically contain a wide variety of constructs, the reader may wonder which constructs are actually measured.

Similarly, the exact targets of rehabilitation interventions, especially in the case of complex and multidisciplinary interventions, are hardly mentioned. Often, only the therapeutic modality (e.g., exercise) or the involved therapeutic professions (physiotherapy, nurse practitioner) are denoted. The authors thus leave it to the readers' creativity to imagine which impaired body functions, limited activities, or restricted participation

were targeted by the interventions provided. Statistical analyses often provide more insight into statistical methods than information about the exact handling of the study variables (e.g., about which variables were included or left out in a multivariate analysis).

Also, most current rehabilitation studies do not analyze the mechanism of action, especially in the case of multidisciplinary interventions. Only rarely are the changes in the intervention targets (e.g., improvement in strength and mobility) explicitly denoted and specifically examined to show that they indeed contribute to the explanation of the change in the study endpoint (e.g., physical function). As recent studies have shown, what explains improvements in the study endpoint may often be surprisingly different from what was initially expected and may relate to confounders (e.g., to changes in anxiety and depression) rather than changes in the targeted body function parameters (113).

It seems, therefore, that the systematic use of the ICF taxonomy and ICF-based standards in the description of the study population, the intervention targets, and the analyses may contribute importantly to the quality, readability, and comparability of rehabilitation studies (114). It is thus suggested that researchers report a categorical profile of functioning of the population under study using the appropriate *ICF Core Set*. To do this, one may use either the *ICF qualifier* or transform measurements made with a clinical test or self-reported instrument into the ICF qualifier using the described qualitative and quantitative mapping methods as described in the previous section (69,70). It is then suggested to report interventions by denoting the relevant intervention target according to the established linkage rules (69,70). With respect to the analysis section, it is suggested to report the variables used in multivariate analyses using again the applicable ICF code.

## SUMMARY

A comprehensive understanding of human functioning and the development of programs to optimize functioning of individuals and populations is provided by the conceptual framework of the International Classification, Disability and Health (ICF). The ICF was approved in 2001 by the 54th World Health Assembly as the shared model and classification of functioning, disability, and health. The acceptance and use of the ICF as a reference framework and classification has been facilitated by its development in a worldwide, comprehensive consensus process and the increasing evidence regarding its validity.

Health professionals all over the world need also practical instruments to apply the classification. In this chapter, we have described the development process of the ICF and different tools related to the ICF. After an introduction in the structure of the ICF, we showed how the ICF categories can serve as building blocks for the measurement of functioning. We then described the current state of the development of ICF-based practical tools and standards such as the ICF

Core Sets and WHODAS 2.0. We illustrated how to map the world of measures to and from the ICF. We also outlined the methodological principles relevant for the transformation of information obtained with a clinical test or a patient-oriented instrument to the ICF as well as the development of generic and specific ICF-based measures. Finally, we reviewed the validity of the ICF and its implementation and application.

The increasing number of publications reflects the interest and relevance of the ICF in research and clinical practice. There is a wide range of putative applications for the ICF. The ICF serves as a unifying framework for the conceptualization of rehabilitation since it is the relevant framework and universally applicable taxonomy for conceptual descriptions and definitions of rehabilitation. In addition, the ICF has the potential to importantly contribute to the quality of rehabilitation care delivery. It can serve as starting point to structure clinical assessment and rehabilitation management. Finally, the systematic use of the ICF taxonomy and ICF-based standards in the description of the study population, the intervention targets, and the analyses may contribute importantly to the quality, readability, and comparability of rehabilitation studies.

## ACKNOWLEDGMENT

The authors would like to thank Prof. Jerome Bickenbach and Dr. Somnath Chatterji from WHO for the inspiring discussions of the ICF and related concepts and Gisela Immich, Susanne Stucki, and Jan Reinhardt for their help in the preparation of the manuscript.

# Systematically Assessing and Improving the Quality and Outcomes of Medical Rehabilitation Programs

## INTRODUCTION

Demands for accountability, improved quality, and the delivery of expected outcomes have grown throughout health care. As the Institute of Medicine's (IOM) *Crossing the Quality Chasm* states: "The frustration levels of both clinicians and patients have probably never been higher. Health care today harms too frequently and routinely fails to deliver its potential benefits" (1). The primary motivation for quality and outcomes improvement systems in rehabilitation, however, is not the avoidance of bad care or patient injury, but the provision of high quality services that improve the function and quality of life (QOL) of persons with disabilities. Public accountability, including justification of the cost of rehabilitation, is an intrinsic part of this fundamental motivation. Medical rehabilitation facilities are caring environments, and the great majority of rehabilitation patients clearly improve in function (2). The technical basis of quality and outcomes monitoring systems for rehabilitation needs to be developed by professionals who are trained to understand the evidence basis of rehabilitation services, working with professionals experienced with clinical practice. The interests of other major stakeholders, including patient or consumer representatives, payers, and government agencies, must also be represented, even though their values may differ (3). The influence, prosperity, and even the survival of rehabilitation as a specialty may hinge on its ability to develop and implement evidence-based monitoring and management systems relevant to consumers, payers, administrators, and policy makers.

A generation ago, rehabilitation—like most of health care—was widely regarded as an applied art rather than a science. It was commonly argued that professionals could recognize quality if they saw it, but it could not be objectively predefined. The possibility of scientific measurement of outcomes was disputed. Progress has been made since then. It is now widely recognized that scientifically valid instruments are a necessary basis for monitoring the quality and outcomes of rehabilitation programs. A large number of instruments and scales are now available in rehabilitation health care, and they are widely applied in clinical and community settings. For example, inpatient rehabilitation

facilities (IRFs) use a standardized assessment protocol, the Inpatient Rehabilitation Facility-Patient Assessment Instrument (IRF-PAI), which includes items from the functional independence measure (FIM) (4). Other current outcomes monitoring systems include the outcomes assessment and information set (OASIS), used in home health settings, and the minimum data set (MDS), used in nursing homes (5). The Centers for Medicare and Medicaid Services (CMS) is presently developing monitoring systems that can be applied across multiple post-acute rehabilitation settings, for example, the continuity assessment record and evaluation (CARE). Ensuring the validity of these instruments to evaluate the variety of needs of rehabilitation patients across postacute settings is a current challenge.

The broad thesis running through this chapter is that quality outcome monitoring and improvement efforts in medical rehabilitation must be based on the best available evidence. This evidence must be integrated with clinical experience, and interventions need to be varied and highly sensitive to individual variations in beliefs, values, and circumstances. Assertions that personal opinions alone should rule will neither advance rehabilitation as a profession nor the welfare of people with disability. While we emphasize the need to ground quality and outcomes monitoring *evidence-based practice* (EBP) and systematic reviews of the scientific evidence, research evidence of effectiveness is typically neither strong nor unequivocal in rehabilitation. Multiple strategies are useful for assuring and improving the quality and effectiveness of medical rehabilitation programs. Monitoring systems need to include measures of both process and outcomes.

In this chapter, we first present basic concepts and principles, necessary for rational communication about quality, outcomes, effectiveness, and evidence. We then review rehabilitation's long experience with program evaluation (PE) and outcomes monitoring systems. Quality improvement (QI), quality assurance (QA), and Joint Commission approaches are then discussed. Because improving the quality and outcomes of rehabilitation programs will require information systems, such systems are then discussed. Other necessary approaches—including professional education, patient-centeredness, and

“clinical practice improvement” (CPI)—are then discussed. Finally, we will discuss key public issues. We hope the chapter is a useful guide and reference work for physicians, administrators, QI specialists, policy makers, and disability advocates concerned with quality and outcomes in medical rehabilitation.

## BASIC TERMS AND CONCEPTS

To discuss quality and outcomes improvement, certain basic terms and concepts need to be understood.

### Evidence-Based Practice

The EBP movement has significantly influenced thinking about quality and outcomes monitoring and related benchmarks, guidelines, PE, and performance indicators. The principles of EBP were originally introduced in 1992 under the term evidenced-based medicine (6). The concepts and techniques rapidly evolved from a focus on medicine and are increasingly integrated into virtually all health care quality monitoring and accreditation systems. Rehabilitation too needs to adopt principles of EBP. It is now increasingly recognized that measurement of functional gain itself provides only very weak evidence of program quality and effectiveness, as patients may improve even without specialized rehabilitation programming. Much stronger evidence—including evidence from well-controlled clinical trials—is required as a basis to infer provision of effective treatment.

Sackett’s classic definition of *evidence-based medicine* is “the integration of best research evidence with clinical expertise and patient values” (EBM, 2nd ed., p. 1) (6). In this chapter, we define EBP as the use of best research evidence in clinical and community practice, both in making decisions about individuals and at the level of policy and procedures, integrating this evidence with clinical experience and clients’ values. Best evidence is no longer a matter of unfettered opinion: it is evaluated by systematic application of a predefined hierarchy of research quality. Key features of high-quality intervention studies include randomization or other methods of controlling for selection bias and case severity, blinding and avoidance of measurement biases, and minimization of attrition biases (7–9). Widely accepted standards also exist for evaluation of the quality of diagnostic, screening, and predictive (7) studies; standards also exist for measurement studies (10–12). EBP and systematic review are core to the modern view of performance improvement systems presented in this chapter. More complete information on EBP is found in Chapter 80.

### Quality and Outcomes Monitoring

PE is the systematic collection and analysis of information about some or all aspects of a health service program to guide judgments or decision about that program. An effective PE involves procedures that are useful, feasible, ethical, and accurate (13). QA can be defined as all activities that contribute to defining, designing, assessing, monitoring, and improving the quality of health care. These activities can be performed

as part of the accreditation of facilities, supervision of health providers, or other efforts to improve the performance of health providers and the quality of health services (14). The term quality assurance (QA) has fallen out of vogue, perhaps because it at one time led to reliance on external policing of clinicians, peer review alone, and other limited techniques. However, QA activities of some type continue to be needed to assure that standards of care are met.

Although PE and QA differ in focus, they are complementary. PE examines programs in relation to stated objectives and is concerned with identifying and evaluating the structure, efficiency, process, effectiveness, relevance, and impact of the program. QA generally focuses on patient-specific practices of health providers and evaluates these practices with regard to standards expected by the peer group or benchmarks of exemplary practice agreed upon by the profession. In addition to program objectives and professional benchmarks, consumer-focused and outcomes-oriented performance/QIs have received increased public and professional attention.

QI involves applying appropriate methods of evaluation and outcomes assessment to close the gap between current and expected levels of quality as defined not only by professional standards but also by consumers and other stakeholders. The Joint Commission on Accreditation of Health Care Organizations (JCAHO) states that the most important reasons to establish an outcome-oriented assessment initiative are to (a) describe in quantitative terms, the impact of routinely delivered care on patients’ lives; (b) establish a more accurate and reliable basis for *clinical* decision making by clinicians and patients; and (c) evaluate the effectiveness of care and identify opportunities for improvement (15, p. 25).

*Quality of care* can be defined in many different ways. “Quality” is always positive connoting activities that benefit the person served in the short- or long-term. The IOM has defined quality as the “degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge” (14,16). In other words, quality involves achieving desired health outcomes to a degree that is consistent with current knowledge of diagnosis and effective treatment.

In addition, quality care also requires treating patients with dignity and sensitivity to their individual needs, expectations, and circumstances. Communication, concern, empathy, honesty, sensitivity, and responsiveness to individual patients have long been recognized as necessary attributes of quality health care (17). Patient involvement is particularly important in rehabilitation and chronic care because engaging motivations is essential to the success of activity and behavioral therapies that work to enhance meaningful functional capacities of people served. Individuals served in rehabilitation not only want to be informed about what is going on but also want to be involved in selection of treatment goals (18).

*Performance indicators.* The terms “performance indicator” and “performance measure” are commonly used to designate key outcomes and processes that need to be measured and reported to judge the effectiveness and efficiency of service

delivery. The choice and implementation of performance indicators are central concerns to performance monitoring and improvement, as objective data are needed as a basis for evaluation. Performance indicators are used in QI and reported to stakeholders such as consumers, payers, governing boards, accrediting organizations, and the public. Joint Commission of Accreditation of Health Care Organizations (JCAHO), National Committee for QA, and government agencies have devoted great effort to develop performance measurement systems over the last two decades.

The term “*outcome*” is used in different ways: *life outcomes*, pertaining to role restoration or QOL; *health-related QOL*, pertaining to aspects of life, experience, or function that are logically related to physical health or recognized mental disorders; and the *outcomes of care*, here, *rehabilitation outcomes*. Rehabilitation improves many quality aspects of patients’ lives; however, it would be naïve to suggest that medical rehabilitation can routinely produce or assume responsibility for total or all encompassing improvements in patients’ lives. Although we are concerned with the person’s QOL as a whole (large circle in Fig. 12-1), medical rehabilitation is primarily directed at health-related QOL (smaller oval). Medical rehabilitation professionals are primarily responsible for those valued aspects of patients’ lives that they can affect, namely *treatment outcomes* (small triangle in Fig. 12-1).

The Joint Commission has defined *outcomes* as “restoration, improvement or maintenance of the patient’s optimal level of functioning, self-care, self-responsibility, independence and QOL” (19). The term also connotes connection to preceding rehabilitative treatments; the outcome in some sense is due to rehabilitation. It is essential to realize that outcomes *due to* rehabilitation are not directly measured: they are inferred from prior evidence and theory and estimated using a data set permitting adjustment for case severity and confounding factors that influence measured outcomes.

*Benchmarking* is basic to both quality and outcomes monitoring. A *benchmark* is a target value of a performance indicator. Joint Commission requires that facilities compare

their processes and outcomes with those known to be attainable elsewhere (20). The Commission on Accreditation of Rehabilitation Facilities (CARF) also writes of benchmarks. Continuous quality improvement (CQI) assumes a scoreboard of process or outcome measures (21–24). Severity or risk adjustment is usually needed to develop accurate benchmarks for evaluating outcomes and processes.

### Treatment Effectiveness

Knowledge of treatment effectiveness ties together processes and outcomes. *Effectiveness* may be defined as the sustained improvement in patient function produced by a care intervention beyond the natural healing and adjustment that occurs with less intensive or specialized care. Assertions that an intervention is effective require evidence, ideally from prior well-controlled studies. Effectiveness is assumed by use of the term “rehabilitation outcomes” and is the core professional attribute of quality medical rehabilitation. Effectiveness encompasses the appropriateness of care, the technical competence with which procedures are carried out, risks, and intended as well as unintended consequences. Both QI and outcomes monitoring systems should be based on best knowledge regarding effective treatment.

### Surrogate Indicators of Effectiveness

In practice, PE and outcomes management in rehabilitation are commonly based on implicit beliefs and practical but flawed surrogate estimates of effectiveness such as functional gain. In PE, the term “effectiveness” is often used to mean how successful a program is in accomplishing its goals or the average amount of functional gain by patients. Higher rates of functional improvement may suggest greater effectiveness in some facilities than others but are far from proving it (25).

Older QI publications have defined effectiveness as “the degree to which the care is provided in the correct manner, given the current state of the art” (19,26). In this traditional view, “correctness” is associated with adherence to normatively based standards and methods of care. Studies in acute hospitals, for instance, have provided correlational evidence that better adherence to the expert-defined best practices would improve patient outcomes (27–30). By contrast, an evidence-based approach would ask about the strength of evidence for various expert recommendations, accepting expert opinion tentatively when there are no strong empirical studies.

### Efficiency and Value

*Efficiency* means delivering appropriate, effective care within cost constraints. Straight *cost* considerations must be distinguished from *cost-effectiveness*, which involves evaluating costs of treatment against gains in patient outcomes. Measures of service use (e.g., length of stay [LOS], treatments units) are often useful surrogates for detailed computations of cost. In a managed care environment, we especially need to know whether the imposed limitations have compromised patient outcomes. In a prospective payment system (PPS) environment, if one spends too much effort on one patient, there

**FIGURE 12-1.** QOL, health-related QOL, and rehabilitation outcomes.

will be fewer resources available for others. Data are needed to guide us in determining where the optimum lies.

Rehabilitative care not only needs to be provided efficiently, but it must also be of *value* to its customers, including most of all patients and also payers (31). Patients, payers, and society commonly demand robust improvement in the patient's functioning and/or QOL that endures in everyday life after discharge. QALYs—quality adjusted life years—are, in principle, applicable to rehabilitation (32,33), but current methods of computing QOL over time have not yet been shown to be sensitive to rehabilitative interventions (e.g., functional gain) or to the decisions that rehabilitation professionals and people with disability must make (see Chapter 18).

Defining and improving the quality of care would be easy if money were not an issue. Resources, however, are always limited. The difficulty of defining affordable value is greatly complicated when available funding varies enormously across patients and no societal decision has been made regarding standards for valuation of the quality of human life over time (e.g., QALYs) (33). As economic constraints have increased and funding for rehabilitation has become more variable, assuring the provision of high-quality care has become increasingly challenging, at least in the United States.

### Levels of Health and Functioning

Health and functioning are rich concepts that involve a number of levels that need to be understood given their central importance to systematic QI. Chapter 19 explains components of health outcomes as defined by the newer *International Classification of Functioning, Disability, and Health* (ICF) (34). In brief, distinctions among functioning at the biological level, the level of the individual *per se*, and the level of the individual in society and the environment (previously designated as impairment—disability—handicap) (35) have been replaced by *body systems and structure*, *activity*, and *participation*. Measures of *pathology*—dysfunction at the cellular or biochemical level—and *disease* are also needed in QI and outcomes management in medical settings. The term *functional limitation* is also valuable to denote specific limitations or activity restriction of the person, compared to a normative average and measured in a controlled environment (36,37).

Impairments are of focal importance in *medical* rehabilitation treatments. Performance monitoring systems in medical rehabilitation must at least group patients by their primary etiology or impairment group, and ideally, severity adjustment is in terms of the primary diagnosis or impairment (e.g., severity and level of paralysis in spinal cord injury) (38). If an impairment is used as an outcome measure, there should be evidence—not merely an assumption—that the impairment is significantly related to functional outcomes or QOL. Numerous medical and nursing conditions treated in medical rehabilitation—infection control, reduction of decubitus ulcers, control of blood pressure, prevention and treatment of deep vein thrombosis, diabetes management, pain relief—meet this criterion. In many circumstances in rehabilitation, however, a pathology or impairment can be treated

and reduced without alteration of the primary disease or the functional status of the patient (39). Range of motion and even spasticity reduction, for instance, are poorly correlated with functional outcomes (40), probably because they are not the primary barriers to improved function for many patients. Discriminating more worthwhile from less worthwhile but still technically effective interventions is a challenge for rehabilitation providers.

Medical rehabilitation deals with all these levels but has long focused on diminishing impairment and improving basic capabilities of persons with disabilities (e.g., reducing assistance requirements in activities of daily living [ADL]). There are currently a number of reasonably reliable and valid scales of functioning that have been developed for various rehabilitation settings (5,41). The FIM, for instance, has been widely studied, and its utility and basic validity for assessment of physical functioning are well established, as are its limitations in the areas of speech, language, and cognition (42). In assessing function, it can be important to realize that activities and disabilities are determined not only by impairments but also by the extent of compensating strengths. Moreover, disability and even indicators of participation may have a loose connection to life satisfaction (38,43).

### Health Status Measures

Medical rehabilitation outcome measures may be considered to be a subcategory of health status and QOL measures. Books summarizing different scales of health-related QOL are now available (38,44–48). These sources are filled with scales relevant to rehabilitation outcomes assessment, though their sensitivity and logical applicability to medical rehabilitation require verification. Perhaps the most commonly used measure of general health is the short form 36 (SF-36) (49), although many other measures are also used (48). Some of the subscales within these instruments appear to be too broad or are otherwise not directed at problems treated in medical rehabilitation, but many dimensions—such as pain relief, general feelings of health and well-being, and physical function—are relevant.

QOL measures are relevant to rehabilitation outcomes assessment. Subjective or affective QOL is so important that it deserves assessment, despite its (nonqualified) exclusion from the World Health Organization (WHO) scheme. *Subjective well-being* and *life satisfaction* have been increasingly studied for use as ultimate rehabilitation outcomes measures (50). Subjective well-being is statistically associated with health and function, community participation, and a loving and satisfying social life, but the inconsistency of these associations demonstrates that subjective well-being cannot be reduced to indicators of objective health and circumstance (43,50): the person's own expectations or implicit standards regarding his or her own life are critical. Chapter 12 discusses QOL assessment in greater detail. At this point, indices of patient well-being are sufficiently well validated to be used in research but have not yet been validated for use as routine indicators of the performance of individual rehabilitation programs.

### Criteria for Choice of Measures

Criteria for choice of measures for performance and outcomes monitoring systems include relevance of content, reliability, other internal psychometric characteristics, or alternatively, biometric validity, and evidence of predictive validity, including evidence of utility in practice (10,13,51–53). While ease of administration and expense are critical considerations in practice, justifiable expense depends on the benefits of the measurement system.

### Standards and Levels of Validity and Reliability

Scales employed in performance monitoring should meet recognized standards of reliability and validity in rehabilitation or other fields (10). While reliability and validity are commonly treated as catch phrases, they in fact subsume a set of inter-related criteria for the quality and utility of measurement. The validity of functional and QOL measures can be understood as a set of criteria for (a) sensible internal structure—that is, whether the set of items or procedures has the needed content, low intrinsic error, desirable internal psychometric characteristics and (b) desired external validity characteristics, including whether it generally “behaves” as it should according to one’s understanding of the construct, including convergent and divergent validity, and evidence of utility in practice, also known as consequential validity—that is, whether the measure leads to correct inferences and verifiable benefits, at least in its major application or use (52,54). If the construct to be measured and the main application are clearly specified, it is possible to grade the quality of measurement evidence (52,54,55).

One needs to know the *reliability*—that is, the stability, agreement, and reproducibility—of measures to interpret them. Without reliability information, one may not be able to distinguish between actual objective differences in scores and mere subjective or chance fluctuations. Error-prone indices of the appropriateness of medical care have been shown to overstate the frequency of inappropriate care (56).

*Validity* is a concept associated both with the construct being measured and with its application. Evaluation of a measurement procedure involves consideration of whether it has necessary internal characteristics (e.g., homogeneity, hierarchical structure) as well as external predictive characteristics, including *validity* for some purpose or construct. *Accuracy* is the relevant criterion to evaluate the validity of a measure when a true “gold standard” is available. *Sensitivity* is the probability of detecting a condition that a person actually has. *Specificity* is the probability that the test gives a negative result among people without the condition. When the question concerns whether an individual actually has a specified condition, given a positive result of a test, the needed statistic is positive predictive validity, which requires also knowledge of base rates (57,58).

When summing items to provide a meaningful summary number, one should know the degree to which the items are internally consistent, that is, additive and unidimensional (58–60). The FIM instrument, for instance, consists of at least two dimensions: motor ADLs and cognitive-psychosocial function (61).

Limited range of item difficulty has also been a problem with some scales used in rehabilitation, since rehabilitation deals with a great range of human performance—from coma or total paralysis through independent living and paid employment. Many existing scales are sensitive to the typical range of improvement seen in medical rehabilitation hospitals (37,42,62,63) but still have ceiling or floor problems, that is, they may be insensitive to very real improvements that occur in some patients who remain at a “total assist” level in ADLs or in individuals who are independent in ADLs but need speed, endurance, or higher level skills to sustain a productive lifestyle in the community (64).

To employ parametric analysis techniques (e.g., reporting means, *t*-tests, or Pearson correlations), the scales employed should have equal-interval characteristics. Measures developed using Rasch analysis have probabilistic equal-interval properties (58–60,65). They can identify and lessen floor and ceiling limitations of older measures, as can other forms of item response theory (IRT) (58,60). The method also has the advantage of identifying “misfitting” persons, that is, individuals whose pattern of functioning is so atypical that the conventional method of scoring their outcomes may be misleading. Different methods of scoring functional scales may be needed for different diagnostic groups. Walking, for instance, is relatively easy for a person with brain injury but is near impossible for a person with complete paraplegia; its significance as a marker of progress is radically different between the two persons. Chapter 11 presents additional criteria for choice of measures.

### Sensitivity to Change and Evidence Bases

Sensitivity to change is a basic criterion for choice of outcome measures. This is true in the sense that outcome or performance measures unrelated to actual treatment objectives and valued outcomes should not be employed. At the same time, a measure can be too sensitive, so that improvement is of little value to patients or can fluctuate due to factors unrelated to treatment. With modern IRT and other metric analysis, it is possible to quantify the degree of sensitivity of a measure, that is, the degree of error of measurement. Previous controlled research provides a superior basis for choice of outcome measures; as such, research can identify attainable outcomes and linkages between outcome and needed treatment processes.

### Severity Adjustment and Statistical Consideration

The need for *severity* or *risk adjustment* of performance data can hardly be overemphasized. QI and outcomes monitoring systems that are unadjusted or poorly adjusted for disease severity, functional limitations, and other factors that affect outcomes are likely to provide misleading reports. While all factors cannot be controlled statistically, outstanding confounding factors can be measured and their effect projected. Finally, knowledge of at least basic statistical principles is needed to interpret performance monitoring data. Sample size is always a consideration: a single bad outcome may well be a fluke; a pattern of outcomes below severity-adjusted norms indicates a possible process problem needing further investigation.

## PROGRAM EVALUATION AND OUTCOMES MANAGEMENT

This section discusses systems of measurement, monitoring, and interpretation focused on the outcomes attained after care. We begin by discussing PE and associated schema in rehabilitation. Rehabilitation facilities—largely under the aegis of the CARF—now have several decades of experience with PE, and the resulting knowledge provides a basis for current program monitoring and clinical management activities.

Rehabilitation is provided in many settings, including transitional care facilities, nursing homes, outpatient clinics, homes, and hospital-based IRFs. Most of our examples will deal with IRFs and the most common outcome measure currently employed in IRFs—the FIM—in order to provide a focus and to limit length. Principles and concepts apply to other settings in which health-related rehabilitation is provided.

### Program Evaluation

PE refers to a variety of information-gathering activities designed to aid in program development or functioning (i.e., formative evaluation) or to decide whether a program, as a whole, is worthwhile (i.e., summative evaluation). Many approaches to PE have been employed over the last three decades (66). “Performance monitoring” is a more current term that includes both PE and monitoring of key processes. Accountability to the public and internal management are overarching purposes regardless of rubric. These systems have multiple uses, including marketing, profitability, program planning and development, research, prognosis, utilization review, and improved clinical planning and treatment.

### CARF and the Program Evaluation

Leaders in rehabilitation have long realized that the field needs to demonstrate its benefits to the public. Beginning in the 1970s, CARF assumed leadership, providing a forum that led to standards that required established rehabilitation facilities to develop PE systems that measure outcomes (67), implemented in numerous rehabilitation facilities over past decades.

PE has been described as “a systematic procedure for determining the effectiveness and efficiency with which results are achieved by persons served following services” (18). These results are collected on a “regular or continuous basis” for all patients or for a systematic sample of patients (18,68). PE and outcomes management involve setting goals and expectancies. If goals are not attained, reasons should be determined and action should be taken. In its usual form, PE does not provide answers to specific problem areas but merely identifies that a problem or strength exists. Answers are identified through more in-depth investigations involving further analyses of data, chart review, examination of quality measures or monitors, and discussions with the knowledgeable staff (18,21,69–72). PE systems are used to help make clinical management decisions and improve program operations.

Realizing the need for objective comparative data, most medical rehabilitation programs have joined large data systems. Accreditation standards state that organizations should compare their results and/or processes to some benchmarks, such as pooled data systems, the organization’s own larger network, and/or the published literature.

CARF has long emphasized meaningful, sustained outcomes in the real world after discharge. The goal is to maximize patient functioning and QOL in the community after discharge. Medical outcomes are noted when these may affect functional or general health outcomes. CARF standards ask that rehabilitation programs assess outcomes in terms of the WHO’s ICF (34) and emphasize the patient’s goals, desired activities, community participation, and satisfaction with services (18).

Experience with PE systems resulted in a shift of emphasis away from choice of measures and formal design of the PE system, and as early as the 1980s, *use* of the PE—not details of system design—became the key point. In the mid-1990s, CARF standards changed to use the terms “outcomes measurement and management” rather “PE” in order to emphasize the need for more operationally oriented approaches.

### The Standard Rehabilitation Program Evaluation Model

In the 1970s and 1980s, medical rehabilitation programs developed their own tradition in PE (68). These PE systems were designed to provide an overview of program outcomes. In effect, they were designed to assure outcomes to the public, that is, to be summative evaluation systems. In operation, however, these systems functioned as formative evaluation systems (70). Information on outcomes is given primarily to program staff, who constitute the main audience for reports. Improved program management was, in fact, a primary expectation, leading to the relabeling as “outcomes management.”

Standard PE systems in rehabilitation have three components: design, goals and objectives, and reports. While this basic model is still widely used, updating has occurred as part of CARF’s strategic outcomes initiative to incorporate notions of outcomes management. CARF offers training, guidance, and materials on outcomes management. Anyone developing, implementing, or using a PE or QI system in rehabilitation should consult a CARF standards manual or Web site ([www.carf.org](http://www.carf.org)) for references to the most recent information (18). Major components of a standard PE system are summarized below.

### Program Purpose and Description

The PE design is based on a mission statement describing who the organization serves, what services it provides, and what goals it expects to accomplish. Goals should be anchored in the concerns of the persons served and other stakeholders—groups or entities with an interest in the success of the program. The special programs that constitute the organization are then described (e.g., stroke program, brain injury, spinal injury, pain program, general rehabilitation, independent

living center). Key influencers are listed to ground the statement in reality. These are external agencies that constrain and direct the rehabilitation program, such as the rehabilitation market and clients, referral sources, patients, staff, Medicare, third-party payers, and key government agencies.

Each program within an organization and the population it serves are to be described:

1. General program objectives. Defining a PE system requires defining program objectives. Foremost among these are anticipated results to the primary clients, but indicators of efficiency are also typically needed.
2. Admission criteria or definition of the population served in the program. Both inclusionary (e.g., cerebrovascular accident) and exclusionary (e.g., free from communicable disease, over 18 years of age, noncomatose, dependent in ADLs and ambulation, medically stable for 3 hours per day of therapy, likely to survive at least 6 months) criteria are defined.
3. Persons served, described with regard to diagnosis, functional issues and problems to be addressed, and relevant demographics.
4. Services provided or readily available to the patient, such as medical care (e.g., physiatry), physical therapy, occupational therapy, speech/language pathology, psychology, social services, nursing, or attendant care.

### General Program Objectives

CARF standards require the measurement of program performance in the domains of effectiveness (results or outcomes for persons served), efficiency (relationship between outcomes and resources used), service access (e.g., number of days from referral to admission, convenience of the hours and location of operation), and satisfaction (experience of the persons served and other stakeholders) (18). Effectiveness, efficiency, and satisfaction have been in the CARF standards for at least three decades, with service access being added to reflect the challenging and dynamic aspects of today's health care environment. Data elements to assess these domains are measured at admission,

discharge, and follow-up, depending on the appropriate time for each data element. Outcomes are assessed after discharge. Follow-up data collection usually takes place 3 months after discharge but other periods can also be justified.

Also needed are progress objectives or intermediate outcomes in terms of patient improvement in the clinical setting toward outcomes such as improved independence in mobility, self-care, communication, or medical self-management. These are similar to (but less specific than) our concept of treatment objectives.

*Efficiency* objectives are also needed. Resources consumed such as staff time, LOS, number of treatment sessions, and dollars should be monitored and related to the results achieved. For example, the functional gain for a given LOS can be monitored to ensure that outcome is not sacrificed with resource restriction.

### Program Evaluation and Outcomes Monitoring Systems in Rehabilitation

For several decades, rehabilitation programs have employed a model of PE. This model is only one of several alternatives; textbooks provide lessons in the variety of approaches and issues encountered in PE more generally (66,73). We describe this standard or classic model because examples of it are comparatively well-defined and tested and because lessons from it provide the basis for current and future performance monitoring systems.

Typical constituents of a rehabilitation inpatient hospital PE system are shown in Figure 12-2. The sparseness of measures (italicized) in the process box and the larger set of admission (i.e., input) and outcomes (i.e., discharge and follow-up) measures show the emphasis of conventional PE systems. Scales of independence in ADLs such as the FIM constitute the primary input (e.g., admission, baseline) and output (e.g., discharge, follow-up) measures. Cost and LOS are classified here as process or input measures because they indicate the degree of effort or *resource use* devoted to benefiting the patient. PE systems also address quality of routine nursing care, hotel services, and patient satisfaction (74,75).

**FIGURE 12-2.** Basic conventional PE framework for rehabilitation programs. Items from the IRF-PAI are shown in *italics*.

The FIM instrument is the most commonly used functional outcomes measure in inpatient medical rehabilitation. It is an 18-item scale that rates each item on a scale ranging from 1 (total assist) to 7 (completely independent). The FIM consists of two overall factors (motor function and cognition) and recent reports indicate acceptable-to-good reliability (65). It became the basis for the PPS for medical rehabilitation hospitals in the United States beginning January 1, 2002.

The most widely used set of rehabilitation performance indicators at present is found in the IRF-PAI data set. This data set contains information on impairment group, FIM at admission and discharge, demographic information, and LOS. General purpose data sets categorize patients so that they can be grouped by estimate expense for the PPS. For purposes of PE or clinical performance monitoring, however, the information system needs to be tailored to diagnostic and functional groups.

PE systems also need supplementary measures used for general descriptive or comparative purposes (see Fig. 12-2). Demographic variables (e.g., age, gender, race) are needed as input or independent variables. Although they typically are not good measures of case severity, demographic variables do help segment the population for other analyses (e.g., access to care, service type).

Data on and reasons for rehospitalization and death are also essential supplementary measures in PE in medical rehabilitation, which treats aged, infirmed, and chronically ill patients. Although the main purpose of medical rehabilitation is not to decrease mortality, certain medical rehabilitation programs have been shown to substantially increase survival (76).

Even though accreditation standards have allowed completely local measures and standards, the flimsiness of completely local, subjective expectancies has been recognized. Acknowledging this, rehabilitation programs have voluntarily created regional and national outcomes data systems such as the Uniform Data System for Medical Rehabilitation, eRehab-Data, ITHHealthTrack, and other firms. The use of normative benchmarks is highly valuable to performance monitoring but provides a challenge when the available benchmark data do not correspond exactly to the program's objectives or population.

### Needed Specification and Additional Design Points

Defining a useful PE system requires forethought, including

- Specification of whom measures are applied to. While traditional program objectives were applied to all patients in the program, newer approaches recognize that important and expected outcomes vary across groups. CARF standards after 1998 require analysis of outcomes in meaningful groupings rather than in all patients.
- Specification of how measures are implemented and when they are applied. Most programs measure function at admission and discharge. Assessment of function 1 to 6 months after discharge gives a more valuable picture of patient outcomes. Follow-up of outcomes has become common and is required by CARF standards. The person who does the measurement should also be specified.

- Specification of expectancies—specific statements of the expected level or range for objective performance indicators. The classic PE model involves specifying a range of performance expectancies: minimal, optimal, and the maximal, thought to be attainable under ideal circumstances. Outcomes were not to fall below the minimum. If they did, action was to be taken (67,68). Expectancies are commonly based on a combination of internal trends and targets, and if known, regional or national norms.

*Consideration of the relative importance of objectives.* In the traditional PE model, program success was to be summarized in a single number. Actual objectives attained were multiplied by weights and expectancies chosen so that optimal attainment of outcome was signified by 100. The weighting system is no longer required, but the concept of weighting outcomes can still be useful.

Additional points for design of outcomes monitoring systems are as follows:

- Cases that stay only a few days are not comparable to full-stay cases and need to be looked at as a separate group. Long-stay outliers also need to be examined.
- Outcomes monitoring systems center on episodes of illness rather than on administratively convenient units such as a stay in rehabilitation. Readmissions need to be collapsed or analyzed separately. Efficiency cannot be achieved by cycling difficult cases back and forth between facilities.
- Some rehabilitation programs distinguish between cases admitted for different reasons. Some patients, for instance, are admitted largely for care of certain medical-nursing problems that rehabilitation hospitals are particularly adept at treating (e.g., decubitus ulcers, urinary tract infections, weaning a patient from a ventilator). Incorporating measures relevant to the reasons for admission and for rehabilitative treatment enhances the meaningfulness of outcomes monitoring reports.

### Outcome Monitoring Models for Different Populations

Patient populations need to be divided into major groups, usually by etiology or impairment group and functional severity. References are available on how to tailor a PE system for

- General inpatient medical rehabilitation, including stroke (37,63,77)
- Spinal cord injury (37,63,78)
- Traumatic brain injury (38,79–81)
- Chronic pain management programs (82)
- Outpatient rehabilitation clinics (67)
- Postacute community reentry (63,81,83) and vocational programs (63,81)
- Other conditions requiring rehabilitation (63,84).

Because inpatient rehabilitation programs must contend with numerous mixed-diagnosis cases, comorbidities, and rare diagnoses, mixed-diagnosis evaluation systems are a necessity if outcomes (and processes) are to be monitored for all patients. Functional improvement is a meaningful, if imperfect, way of quantifying the

benefits in mixed-diagnosis groups. Mixed-diagnosis systems that focus on functional and participation-level outcomes appear to be relatively successful for later stages of rehabilitation, including transitional living, community integration, vocational rehabilitation, and long-term nursing home care. Both function and diagnosis are critical in evaluation of processes and outcomes of inpatient, outpatient, and at-home medical rehabilitation programs.

## Outcomes Measurement

This section examines issues distinctive to the measurement of *outcomes* for rehabilitation PE.

### Generality of Measures

PE goals have been designed to credit the program with the larger benefits it produces, such as independence from assistance (68). These goals are more general than treatment or case management objectives. Measures of long-term outcomes in the community are valuable for marketing and are ultimately needed for policy and accountability (69,70). Data on how a program has reduced the frequency with which patients are institutionalized in nursing homes and hospitals after discharge, for instance, are meaningful and even influential with boards of directors, government officials, insurers, families, and referral sources. While reports of such benefits are useful in communication of the benefits of rehabilitation to the public, more proximal outcome measures are usually more closely related to interventions and hence are more likely to be related to action to improve clinical processes.

### Performance Versus Ability

The standard and usual practice is that primary outcomes are measured in terms of actual patient performance, preferably measured in the community after discharge, rather than in terms of capability demonstrated or judged in the clinic (63,68,84). This is because actual performance is usually a more reliable and objective measure than judged ability, and activities in the community are more meaningful and valued than activities in the clinic. Abilities that are used in practice *prima facie* provide greater benefit than those used in artificial situations. Exceptions exist when dealing with performance capabilities that are important though infrequently needed (e.g., safety skills) or if there is evidence that the clinical performance has high validity as a proxy for real-world outcomes.

### Timing of Outcomes Measurement: Follow-up

Outcomes for persons served are best measured following discharge (68). Measurement at discharge is less expensive but may be less informative, as clinical staff are already aware of patient function at discharge. Information on durability of outcomes is valuable. Patterns of under-preparation, or of long stays by patients otherwise ready for discharge, should be actionable. Whatever time is chosen, data need to be obtained from all persons served or from a representative sampling (18).

There is no perfect time for follow-up, as there are contrasting advantages to both short-term and long-term follow-up.

Three months has been the most common period for follow-up of rehabilitation outcomes, but periods of 1 to 6 months after discharge are also found. Rehabilitation involves enhancing healing and adaptation processes, so recovery processes should ideally be measured repeatedly over time.

Outcomes after discharge are usually assessed by telephone calls or clinic visits. PE systems in rehabilitation have long employed telephone follow-up. A great deal of research has shown that telephone follow-up using structured questionnaires of demonstrated reliability and validity (10) provides a good balance of reliability, low rate of missing data, and modest-to-moderate costs. The number of self-report scales for assessing health and function with basic knowledge of reliability and validity is now large (37,42,44–47,62,85,86). In-clinic follow-up methods are required to objectively assess medical problems. Missing data, however, can be a problem if patients do not return for their follow-up visit in the clinic. Tele-rehabilitation technologies may improve our capacity to provide objective patient assessment following inpatient discharge.

Practical difficulties of follow-up include its expense, funding restrictions on continuing outpatient care, a lack of payment for educational or evaluative follow-up, and the fact that continuing outpatient care may involve a different provider than inpatient care. Nonetheless, rehabilitation programs can be improved by ongoing knowledge of whether new, unexpected problems or complications arise after discharge, and if so, to whom and why. Monitoring of long-term outcomes is also needed to assess whether changes in health care designed to control costs have compromised the health or functioning of patients undergoing rehabilitation.

## Benchmarking Functional Outcomes

The availability of benchmarks or standards of comparison is basic to systematic QA and QI. While they may be obtained from many sources, including the published literature, contemporary benchmarks are most commonly obtained from shared data systems that pool data from a number of facilities. The typical outcomes benchmark in rehabilitation has been average functional outcome or gain for major diagnostic groups. Accurate adjustment for case mix and severity is essential for meaningful comparison of raw quality and outcome indicators across patient groups and programs.

### Severity Adjustment for Functional Outcomes

To compare a program's outcome or improvement scores to a benchmark, one should examine major factors that drive these scores. There are a number of factors that generically affect functional outcomes across many diagnostic groups in rehabilitation (25,37,60,87):

1. Functional severity at admission. Improvement may not be equally likely or meaningful across all levels of an admission measure. Some studies have reported curvilinear relationships, that is, greater improvement among patients admitted at intermediate levels of severity (25,87).

2. Chronicity (i.e., onset-admission interval). After the acute phase of many severe injuries, there is a period of relatively rapid recovery, followed by increasingly slow improvement and eventual asymptote, at least on a group basis. Control for natural history recovery curves is needed.
3. LOS. Improvement in rehabilitation tends to be correlated with LOS.
4. Differences in comorbidities and severity of illness or injury (38). Differences in improvement across facilities may be due to differences in medical-nursing severity or case mix. Diagnostic complexity and comorbid conditions adversely affect outcomes and increase LOS in rehabilitation (88). Further development of indices and models of such factors is needed to identify patients with high medical-nursing needs and to establish clinically useful performance benchmarks for them.

Longitudinal research has identified relatively powerful outcome predictors within diagnostic groups. General severity of disease or impairment is typically a major predictor (e.g., severity of spinal paralysis and American Spinal Cord Injury Association [ASIS] motor scores in spinal cord injury [SCI] (38), Glasgow Coma Scale and duration of unconsciousness or posttraumatic amnesia for traumatic brain injury [TBI] (42), severity of paralysis as measured by Fugl-Meyer Motor Scores in stroke (89)). Premorbid factors can be powerful predictors of long-term community outcomes after rehabilitation, even more powerful than severity of injury (90). A great deal of research has been done on predictors of outcome following rehabilitation, and this research is applicable to quality outcomes improvement.

There are several methods of case mix or severity adjustment for medical rehabilitation (91). As methods of risk or severity adjustment, all these are approximate and typically predict a minority of the variance of LOS or functional gain. Rankings of acute hospital outcomes are sensitive to the method of adjustment employed (92). One would expect similar results for rankings of rehabilitation hospitals by functional gain.

### Function-Related and Diagnostic Groups for Prospective Payment

Function-related groups (FRGs based on the FIM) were developed to adjust inpatient medical rehabilitation caseload for case-mix factors affecting LOS (93). Relabeled case-mix groups (CMGs) are now used as a basis for the Medicare's PPS for patients admitted to inpatient rehabilitation programs in the United States. CMGs group patients based primarily upon admissions FIM and impairment group. Average LOS can be projected. FIM-FRGs predict about 31% of the variance of LOS in rehabilitation, which is similar to the performance of diagnosis-related groups (DRGs) for acute hospital LOS. FRGs and CMGs are more detailed than previous PE systems that reported by broad etiologies. Strokes, for instance, were grouped into multiple diagnostic-functional subgroups (94). FRGs classify rehabilitation patients into groups that are more clinically homogeneous and interpretable than groupings by primary diagnosis alone. FIM-FRGs have been used

to investigate the "efficiency" of rehabilitation, that is, the relationship of functional gain to cost or LOS (95).

The main use of FRGs/CMGs is as case-mix adjusters to identify groups whose costs are higher or lower than expected. They are used to identify patients whose LOS exceeds the average for the FRG. They are, however, potentially applicable to analysis of efficiency and QI in rehabilitation, defining patient groups whose gains in function are unexpectedly low given LOS (94,95).

### Functional Gain as an Indicator of Quality

It was once thought that functional gain would provide a robust indicator of the quality of rehabilitation programs. While greater gain in function is undoubtedly desirable, research connecting functional gain of actual ongoing rehabilitation programs to indicators of care processes or program characteristics is scarce. Recent, relatively large studies have failed to find an appreciable correlation between staffing intensity and other characteristics of inpatient rehabilitation programs and severity-adjusted functional gain (87). Functional outcomes and LOS, however, are relatively predictable, and managed care clearly constrained LOS in rehabilitation hospitals. "Relationships between rehabilitation practices and functional gains by patients do not appear to be either simple or overt" (87). With continued research, one may expect that reliable connections will be identified between characteristics of certain kinds of rehabilitation programming and certain severity-adjusted outcomes for selected patient groups.

### Measurement and Statistics: Summary

Medical rehabilitation has reached agreement on basic typical domains for inpatient programs (e.g., mobility and self-care ADLs in the FIM), but measures of other critical domains still have to be developed or agreed upon (e.g., measures of treatment objectives clearly linked to therapies prescribed, extended or instrumental ADLs, ecologically valid measures of communicative and cognitive outcomes, patient satisfaction, and family and other environmental factors) (10,38,42,44). Methods of statistical control for severity of disease, comorbid conditions, and environmental factors that affect outcomes have been inadequately developed.

### Outcomes Management

The term "outcomes management" has become increasingly popular. The term is loosely associated with outcomes measurement, PE, case management, and managed care (84). Paul Ellwood provided the original conceptualization of outcomes management as "a technology of patient experience designed to help patients, payers, and providers make rational medical care-related choices based on better insight into the effect of these choices on the patient's life" (96). Outcomes management is based on the increasingly scientific basis of medical care, including the increasing ability to predict outcomes, and on advances in measurement of health and function at the level of patient experience rather than at the level of mortality

or disease rates. Professional analyses of huge databases were to provide estimates of the effectiveness and efficiency of medical services in practice. Rather general outcomes measures were to be used, so implications would be primarily at the aggregate level—for systems of intervention or programs rather than for management of individual patients.

Outcomes management has also been used to refer to systems that manage individual patients. We define a *clinical outcomes management system* as one that involves routine monitoring of the treatment objectives for individual patients and indicators of patient responsiveness to treatments. Clinical outcomes management, as defined here, differs from traditional PE in that standard goals are not routinely applied across a group but are modified to fit the individual. Treatment objectives and outcomes need to be risk adjusted, necessitating a computerized system. Objective measures are possible for important, high-frequency objectives and outcomes.

CARF's *Standards Manual* treats information management and service delivery improvement—also called outcomes management—in general terms:

CARF-accredited organizations are proactive. The organization continually collects data from a variety of internal and external sources. These data are analyzed and the results are used to make decisions (18).

Human service organizations exist to make a difference in the life of the person served. Evidence that an organization does make a difference comes from information about the outcomes achieved and satisfaction with service delivery from a variety of perspectives. This collection of information is based on the establishment of a level of performance to be achieved prior to measure indicators (18).

CARF has fostered discussion toward indicators for outcomes management (97) but has not specified details (18).

Outcomes management in medical rehabilitation involves four techniques:

1. The use of treatment guidelines (or standards) to help clinical professionals to evaluate patients and choose appropriate treatments.
2. Routine and systematic measurement of both indicators of disease and of patients' functioning, health, and well-being and of changes in these related to the likely effects of treatments.
3. Combining data on inputs (severity), processes, and outcomes into large databases to permit scientific analyses.
4. Analysis and dissemination of results in a form useful to different stakeholders.

Although U.S. health care as a whole is far from operationalizing Ellwood's grand vision for outcomes management, elements of it are being implemented on a piecemeal basis as integrated health organizations create their own clinical databases and smaller organizations voluntarily join health outcomes databases. Rehabilitation, with its long experience with outcomes-oriented PE systems, should be ready to operationalize outcomes management.

### CARF Performance Indicators

CARF has historically been oriented toward outcomes, but CARF standards increasingly use the term "performance indicator." CARF has worked to develop performance indicators for rehabilitation programs (97), attempting to meet the concerns of the major stakeholders to the rehabilitation process. Core questions have been addressed: What does a stakeholder want to know about a program's performance in order to assess its quality and choose among programs? How should these concerns be quantified? Key concerns and draft indicators have been identified for further development.

Many of the proposed indicators are outcomes oriented (97). Outcome concerns include percentage of clients reporting improvement after service provision; durability of outcomes; functional gain; increased productivity, participation, and activities; reduced impairment and disability; satisfaction with processes of care; satisfaction with results of care; QOL after care; efficiency concerns; reduced downstream costs; and value (outcome relative to cost). Examples of possible outcome indicators include

- For "durability of outcomes"—percent of persons in a program who maintain or increase level of motor function from discharge to follow-up or percent of persons who have not been rehospitalized for the same impairment within 6 months of discharge.
- For "satisfaction with results of care"—percent of persons with mobility impairments who respond "satisfied" or "very satisfied" to the question "How satisfied are you with the amount you are able to move around outside following your rehabilitation?"

Structure and process indicators are also proposed:

- Structure concerns—types and numbers of persons served, staff credentials and education, legal status of organization, accreditation status.
- Process concerns—cost and resource use, communication effectiveness, involvement of persons served in rehab decisions, collaboration of providers with payers.

Specific performance indicators and data set are not yet required by CARF standards, and CARF does not endorse or specify any particular measure, tool, or vendor for outcomes management or PE. Indicators or measures employed should be implemented in such a way that stakeholders can know they are looking at comparable information from different programs (97). Though still incomplete, CARF publications and standards continue to serve as a guide for the kinds of indicators needed.

### Critique of Program Evaluation and Outcomes Management

The standard PE model has a number of strengths. It provides an overview of primary patient outcomes, progress, and cost. If used with a shared national or regional data system, standard PE systems provide an index or benchmark of the

effectiveness of the program in improving patient function and placing patients in community settings. Efficiency, or at least an operational utilization review system, is demonstrated if the facility shows a direct correlation between cost or LOS and improvement (25,67) and if improvement/day rates are similar to those in other rehabilitation facilities for similar diagnostic-functional groups. PE data have numerous administrative and clinical uses (84). PE systems have begun to tell us whether rehabilitation programs attain an outcome for their patients.

A drawback of the classic PE system has been that when performance expectancies were not met, a common response was simply to change the expectancy. Without accurate statistical methods of adjustment for case mix and severity, outcome comparisons can be misleading. Without transparency—the ability of outside scientists or professionals to check results and inference—the integrity of results cannot be verified. Without public release, motivation for the system is weakened. In sum, the evaluation and especially the link to action have been weak in PE model, and relabeling such as “outcomes management” has not cured the problem. Nonetheless, the process has taught rehabilitation much about clinical data systems and realistic outcome expectations.

## QUALITY ASSESSMENT AND IMPROVEMENT

To ensure quality in medical care, it should meet standards that are in some sense predefined (20,98,99). Although efforts to systematically ensure quality in medical care go back to the first quarter of the 20th century, pressure for accountability has increased in recent decades, driven by explosive growth of costs and by higher expectations of medical care (98). The federal government and the Joint Commission have been major institutional forces behind quality assessment for hospital care, and historically, CARF has played an important role in defining quality in rehabilitation (18). This section will begin by discussing total quality management (TQM) and CQI techniques and their application to medical rehabilitation. Discussion of QI terminology and then Joint Commission accreditation will follow.

### Total Quality Management and Continuous Quality Improvement in Health Care

An important insight of TQM and CQI (22,23), based on experience, is this: quality and effectiveness primarily depend on the routine system. The root causes of problems are more commonly at the level of the system or the sequences of care processes than at the individual or even department level. The causes of error or undesirable variation in the sequence of activities must be identified and rooted out. The aim is to improve systems not blame individuals. Improved protocols for activities and processes need to be developed and implemented as a key element of QI (74,100). Global organizational commitment is the dominant requirement (22,24,74). The philosophy has moved health care toward improving routine processes.

In practice, TQM and CQI emphasize knowledge of effective processes and involvement of the staff directly involved in the process. They involve fact finding, emphasize prevention of problems, and use measures of processes or of shorter- or longer-term results, depending on the problem. In Deming's terms, “profound knowledge”—detailed, expert, first-hand understanding—of what is really happening in the organization and of the complex processes involved in producing a product is required to improve quality; knowledge of “general variation” (i.e., statistics and scientific measures) alone is insufficient (22,23,101). The emphasis is on understanding the total system and involvement of everyone to diagnose, plan, and fix problems or improve systems. Both the specific problem and systems in which it is embedded need attention. CQI emphasizes review of systems and sequences rather than discrete inspections (21). One must acquire extensive knowledge about the system, not just identify errors or outliers as in traditional QA. When variations exceed normally observed limits, knowledge of the system is needed to infer the cause and mend problematic processes.

To improve medical care, knowledge of diagnosis and treatment alternatives as well as an evidence basis is required. *Clinical practice guidelines* are, if well-developed and based on evidence, invaluable tools for QI, so valuable that we treat them separately in subsequent sections. Guidelines need to be integrated with and adapted to actual team processes to assure and improve the quality and effectiveness of care.

The superior effectiveness of improving routine processes, compared to simply trying to eliminate the worse problems or the worst performers, is graphically displayed in Figure 12-3. This conventional display assumes that measured quality or results are distributed normally. An approach aimed at eliminating unacceptably poor care would, if successful, eliminate poor care for only a small fraction of patients (the small left tail of the distribution). An approach aimed at improving the process of care and eliminating inappropriate variations in the process (see Fig. 12-3) would improve results for most patients. As a by-product, the fraction of results or care that is clearly below the old threshold is also greatly diminished.

As with CQI in other industries, the majority of problems, especially remediable ones, in medical settings are usually problems with systems or procedures rather than with the incompetence of individuals. Many works give examples of systems problems (e.g., nursing care or hospital pharmacy) (1,21,102). By contrast, the claims history of individual physicians, for instance, only weakly predicts future claims proneness so use of such data to target individual physicians is problematic (103). Malpractice claims data have been used to identify problem-prone clinical processes and to suggest improvements to reduce the likelihood of negligence (30).

Another insight is that QI systems that *depend* on mass inspection of discrepancies in outcomes are often ineffective or inefficient (21,74). If QI simply counts errors and points them out to staff, QI can be perceived as an unpleasant policing activity, and the substantial effort to detect outcome anomalies may not be paralleled by efforts to improve production or treatment processes. The problem is not that outcome measures are wrong

**FIGURE 12-3.** Traditional QA versus QI.

but how they are used: data should function as scoreboards for team efforts to improve their own processes (23). Multiple statistical approaches are needed, including process and outcome measures to both identify defects and verify improvements. CQI integrates knowledge, processes, at least short-term outcomes, and action to improve them.

The literature now reports many examples of successful system improvement in health care organizations, especially hospitals. Limited quantitative evidence of effectiveness exists (104), but CQI and TQM are difficult to test as they transcend any particular setting or method. TQM has often been implemented by managers and applied to administrative organization so that clinicians have difficulty seeing its use to improve clinical processes. CQI/TQM teams led by clinical professionals may have a different experience.

Experience has shown that approaches to quality and outcomes improvement from manufacturing or provision of hotel services need major modifications to be applied to health care. Patients are not uniform material input to a manufacturing process, and customer satisfaction is not the only, or even the primary, relevant outcome in health care. Rather than being assumed or predicted on the basis of processes, patient responses to treatment must be tested in controlled research and monitored in practice. Comorbid conditions and idiosyncratic patient characteristics and needs alter ordinary patterns of treatment and response. “Context” has fundamental effects on activity therapies in rehabilitation (105). The principle

of reducing variance in processes is relevant to parts of rehabilitation, but quality rehabilitation also involves the tailoring of treatments to the priority needs of the individual.

### Professional Quality Improvement Terminology

A few basic terms assist in professional assessment and improvement (98,106). *Norms* are measures of actual clinical practice. Examples are average LOS, average improvement in FIM scores, and average hours of physical therapy. Norms are most clinically useful when they are specific to a patient diagnosis or otherwise graded to patient characteristics. Benchmarks apply to processes as well as outcomes. Rehabilitation professionals need to have benchmarks against which to compare their staffing, education, costs, initial evaluation, intervention types and intensities, patient satisfaction, and short-term outcomes as well as long-term ones. Norms and benchmarks have greater authority when they are based on large samples or when they tell us what is done and achievable by the “best” or at least better programs.

*Criteria* are statements that define appropriate or correct clinical care (98,107). Criteria are typically developed on the basis of professional experience and scientific literature. Some distinguish between a criterion and a *standard* (108), using the former as the more general dimension and the latter as the specific numeric cut-point. We will not rigidly distinguish the two, because a general dimension separate from a quantitative decision point is of little use (98). For instance, the statement that “stroke patients will have a blood level of Coumadin in the therapeutic range” is useless without specification of what the range is (e.g., prothrombin time of 1.2 to 1.5× control). Another example of a criterion or standard is the assertion that inpatients in medical rehabilitation should receive 3 hours per day of combined therapy (physical, occupational, and speech and language pathology). Criteria and standards may describe structure, process, or outcome, and in practice involve all three.

### Sentinel Events

In practice, action to maintain quality of care frequently depends on *sentinel events* (109)—single occurrences that are highly problematic or socially unacceptable. Litigation following patient injury, staff quitting over unacceptable quality or ethical issues, and cockroaches on the walls are not definitive evidence of global quality problems, but they should motivate a review to determine whether there are remediable problems. Sentinel events require a response. The point of systematic QI is to go beyond concern for negative outliers alone.

An *indicator condition* is a frequent, treatable clinical situation (98,101). In Joint Commission terms, an *indicator* is a specific instrument to measure an aspect of care to guide the assessment of performance (110). Clinical indicators point to clinical processes or procedures that need further analysis to determine if improvements can be made. Improved clinical procedures should lead to improved outcomes.

A *threshold* indicates a preestablished point in an *indicator* that should trigger more in-depth investigation to determine whether a problem or opportunity to improve care

exists (98). As an example, a threshold of 5% might be set for rehabilitation patients discharged back to acute care and 15% to a nursing home. In the past, thresholds have been either rather arbitrary or set by expert judgment; some have suggested statistical criteria (98,111,112). The Joint Commission has had difficulty in setting and implementing thresholds. Benchmarks based on both regional and local experience are needed to set thresholds.

There are situations where a 0% or 100% threshold is needed (98,113). For sentinel events, such as death or suicide within rehabilitation or within 7 days of discharge, a threshold of 0% would be justifiable: every case needs to be individually reviewed. In general, however, thresholds of 100% success or 0% problems are unrealistic. Setting thresholds at less-than-perfect levels avoids disproportionate use of time to evaluate a few discrepant cases that will probably be found to be clinically justified (98,114). QI in rehabilitation usually requires discrimination and amelioration of frequently occurring or significant problems, not indiscriminating compulsiveness.

The term “monitor” has been commonly used to describe any routinely collected measure on a group of patients. Staff engaged in activities to improve or oversee care *monitor* aspects of these processes or their outcomes. Because formal indicators have yet to be validated, QI efforts for rehabilitation must be undertaken with the use of ad hoc monitors. Specific Joint Commission indicators are discussed below.

### Statistical Issues

Statistical control principles are as relevant to quality monitoring as outcomes monitoring. Sample size needs to be specified to set a threshold in QI. A 20% rate of apparent error with five patients is very different from the same rate with 50 patients. Patient groups for which indicators are applied must be well-defined. Interpretation of process and intermediate outcomes data is greatly facilitated by severity adjustment, just as with monitoring of long-term outcomes.

### Joint Commission Approaches and Standards

Joint Commission standards have evolved over the years, and there are lessons in this evolution. Structural and process indicators of quality were first propounded. Care had to be provided by licensed practitioners with certain staffing patterns and authority relationships. Extensive record keeping, facility, and equipment standards were prescribed. Although certain structural indicators have been retained today, emphasis has shifted. The aim now is to improve the actual provision of high-quality, effective care, not just to assure the capacity to do so.

In past decades (1950s through 1970s), great reliance was placed on peer review, methodologies for which became increasingly elaborate and focused. Although peer review methods remain useful in certain circumstances, the method came to face increasing criticism. There was little evidence that it improved the actual process or effectiveness of care provided, although it did improve medical records. Current health data systems also face the challenge of proving that they improve care and outcomes rather than record keeping.

Ideas of objective indicators or monitoring, introduced into Joint Commission standards during the 1980s, are now increasingly operationalized in terms of systems of standardized severity-adjusted, objective performance indicators (98), arbitrarily labeled ORYX. Only implicit standards and thresholds exist for many conditions in rehabilitation, but the movement is clearly and strongly toward objective ones.

Prior to 1992, standards were organized around departments and services, distinguished processes and outcomes, and defined specific leadership responsibilities. Influenced by TQM and CQI, the departmental focus was de-emphasized, and the chapter on “Improving Organizational Performance” treats both quality and outcomes issues. “Quality assessment and improvement” was replaced by “QA” in the 1992 Accreditation Manual for Hospitals (AMH). Joint Commission now emphasizes continuous improvement of organizational performance, the identification of processes that most significantly impact care effectiveness or patient outcomes and their improvement, and integration of systems and processes across departments and functions.

### Current Standards

“Helping Health Care Organizations Help Patients” is the Joint Commission’s new tagline, encapsulating a commitment to the public and to organizations that it accredits (115). It also reflects ongoing efforts to enhance the value of accreditation and its utility. Joint Commission standards today emphasize care processes as well as structure. Objective indicators of care processes and linked indicators of care effectiveness (outcomes) are increasingly required. Current Joint Commission standards relate to care and assessment of patients, patient education, consistency across the continuum of care, environment of care, management of human resources (staff competency assessment and training), management of information, infection control, patient rights and organizational ethics, leadership, governance, nursing care, medical care, and improving organizational performance (20). The Joint Commission evaluates quality of care in terms of the degree to which health services for individuals and populations increase the likelihood of desired health outcomes and are consistent with current professional knowledge (115). More specifically, they look at *what* is done, whether care is *appropriate* and *efficacious* for the patient, and *how well* it is done—the degree to which care is *available* in a *timely* manner, is *safe and effective*, is *respectful and caring*, and is *continuous* with other care.

The Joint Commission requires that “the leaders establish a planned, systematic, and organization-wide approach(es) to performance improvement” (115). The performance improvement plan is to be based on the organization’s mission, vision, and values. The plan is to reduce variation in processes and outcomes, increase patient satisfaction, decrease or control the cost per patient, and increase the effectiveness of information management. Performance improvement efforts should be prioritized according to (a) expected impact on performance; (b) high-risk, high-volume, or problem-prone processes; (c) relationship of potential improvement to Joint Commission dimensions; and (d) organizational resources.

There are several methods that health care organizations can use to implement performance improvement. These methods include a ten-step method outlined by Joint Commission in the past and the Deming cycle or the plan-do-check-act (PDCA) methodology (116). The focus PDCA method specifies (F) finding a process to improve, (O) organizing a team, (C) clarifying the current knowledge, and (U) uncovering root cause of variation, before (S) starting the PDCA cycle. These methods include the following (20):

- *Plan.* Planning is multidisciplinary, includes input from relevant stakeholders, and includes an understanding of the current process and outcomes.
- *Implement.* Implementation involves developing potential solutions, benchmarking best practices, and pilot testing new processes.
- *Check.* New processes and processes that involve risks must be monitored and measured. To measure performance, a hospital collects data on processes; outcomes; a comprehensive set of performance measures (indicators); high-risk, high-volume, and problem-prone processes; and other sensors of performance.
- *Assessment.* Assessment is defined as transforming data into information by analyzing it (20). Benchmark data, trends over time, and adherence to regulatory requirements are all useful in determining whether a process improvement has been successful. Appropriate statistical quality control techniques are to be used.
- *Improve.* Once improvements have been realized, process changes need to be standardized and gains maintained.

The Joint Commission has defined general elements of inpatient rehabilitation (e.g., a requirement for assessment of “functional rehabilitation status”) (standard tx.6 (20)). Detailed standards and indicators for inpatient or outpatient medical rehabilitation programs have not been established at the time of this writing, but standards and indicators for related areas of health care may be informative (e.g., standards manuals for home medical equipment, respiratory therapy and rehabilitation technology (117), ORYX indicators for home care (118)).

### Data Collection Recommendations and Standards

The Joint Commission considers measurement and data collection to be the foundation for performance improvement activities (20). The organization’s leadership is responsible for establishing an information system to monitor quality-related events. The Joint Commission requires that

1. Organizations collect data to monitor performance (20).
2. Data are systematically aggregated and analyzed.
3. Information from data analysis is used to make changes that improve performance and patient safety and reduce the risk of sentinel events (115, p. PI-7-9).

Arbitrary thresholds and standards particular to a program are not enough. Benchmark values may come from an external multifacility database, the published research literature, and other sources.

To maximize the impact of limited resources, QI and data collection efforts should focus on high-volume, high-risk, and problem-prone processes. Additional foci include

- Patient outcomes (e.g., functional improvement in rehabilitation)
- Targeted areas of study (e.g., a new or redesigned process)
- Comprehensive performance measures
- Client needs, expectations, and feedback (e.g., patient satisfaction)
- Infection control measures (e.g., urinary tract infection rates)
- Safety of the environment (e.g., hazard surveillance monitoring)
- Quality control and risk management indicators (e.g., medication incidents, patient falls)

The Joint Commission has developed more stringent patient safety standards in recent years. Prevention of errors is a major focus. Effective in 2002, health care organizations were mandated to perform at least two Failure Mode and Effect Analyses (FMEA) annually (20). An FMEA analysis is similar to a root cause analysis but is proactive rather than reactive. For example, rather than reacting to a sentinel event, an FMEA analysis is performed before a negative outcome occurs. The organization first identifies a high-risk process (e.g., maintaining security of medication carts) or population (e.g., admitting and monitoring ventilator-dependent patients). “Sentinel Event Alerts,” published by JCAHO, may be used to identify patients or processes at high risk. The next potential “failure modes” or hazards are identified, and the process is redesigned to minimize potential risk. “The 2008 National Patient Safety Goals have been expanded to address early recognition and response to significant changes in a patient’s condition, as well as the complex challenge of managing anticoagulation therapy” (115, p. FW-1).

### Performance Indicators

The Joint Commission has devoted considerable attention to developing and identifying appropriate performance measurement sets or systems. Difficulties have been encountered, and development continues after more than a decade of work. Priority was given to high-volume, high-risk, or problematic clinical practices. Most performance indicators developed thus far are short-term clinical indicators for acute medical conditions rather than long-term outcomes, structure, or processes measures. Indicators developed have been subsumed into what is now called the ORYX initiative (described below). Health care organizations are required to send data to an approved data organization on a continuing basis.

The Joint Commission’s *National Library of Healthcare Indicators* describes over 200 measures of clinical conditions, functional health status, or satisfaction in a standard format (110). Key hospital-wide processes—infection control and prevention of medication errors—have been a special focus. The Agency for Health Care Research and Quality now operates the National Quality Measures Clearinghouse

(<http://www.qualitymeasures.ahrq.gov/>) and distributes a database (CONQUEST 2.0) that describes numerous sets of performance indicators for many important clinical conditions and settings (119). In these listings, single measures are becoming the exception: sets of measures—specifying very specific patient groups or subgroupings of patients, processes, and outcome indicators—are required to evaluate quality.

According to Joint Commission, three types of performance indicators are acceptable: (a) “clinical indicators,” (b) health status scales, and (c) patient perceptions of care and service. Clinical indicators evaluate processes or proximal outcomes of care and must be condition specific, procedure specific, or address important functions of patient care (e.g., medication use, infection control). Health status scales may address health in general or in relation to specific patient conditions. Patient perceptions and reports are also accepted, including patient satisfaction with services, effectiveness of pain management, adequacy of information and education provided, and perceived changes in health.

### **Core Measures**

Joint Commission has been developing a standardized set of consensus and evidence-based “core measures” or indicators to be compared across health care organizations. An initial set of core indicators was developed and tested for certain conditions commonly seen in acute-care hospitals, including acute myocardial infarction, heart failure, community-acquired pneumonia, pregnancy, and related conditions. It is anticipated that core measures will be developed for rehabilitation facilities in the future. Effective January 1, 2008, accredited hospitals must select core measure sets from listed performance measure systems that meet accreditation requirements. A complete list of measurement systems can be found at the Web site: <http://www.jointcommission.org/PerformanceMeasurement>.

### **Performance Measurement Systems and ORYX**

Performance measures accepted by Joint Commission are given their ORYX seal of approval. This “initiative integrates outcomes and other performance measurement data into the accreditation process. ORYX measurement requirements are intended to support QI efforts” (115, PM-1).

There are now over 200 performance measurement systems with over 8,000 indicators, and the number increases regularly (<http://www.jcaho.com/pms/oryx/index.htm>). Qualified performance measurement systems have transmitted their data to the Joint Commission since 1999. Health care organizations are required to select a number of measures (currently, six) and to report their data to Joint Commission on a quarterly basis. Since 2000, Joint Commission surveyors have been provided with organization-specific presurvey reports, with ORYX data, to use during the accreditation survey. More standardized, evidence-based “core measures” are being developed to enable more rigorous comparisons. The long project of development and validation of indicators, still underway, should ultimately

enable accreditation decisions to be based more directly on the actual performance of the health care organizations.

### **Indicators for Rehabilitation**

Joint Commission standards describe rehabilitation outcomes in general terms as involving “improvement of functioning, self-care, self-responsibility, independence, and QOL” (20, p. tx.7). Actual rehabilitation-specific indicators, however, are still under development. Many of the indicators discussed above, such as satisfaction with care, infection control, and medication monitoring, are also appropriate to medical rehabilitation (120,121). Quality indicators for nursing practice are becoming increasingly well-defined, with available benchmarks (122).

The FIM instrument is currently an accepted health status measure for rehabilitation. Rehabilitation facilities currently submit FIM data as indicators (e.g., change in FIM rating from admission to discharge). FIM ratings at discharge, LOS, and number of days from onset to admission might also be submitted. The rate of unplanned program interruptions, acute hospital discharges, and discharges to nursing homes might also be employed as problem indicators, as they have been employed for decades in rehabilitation PE.

Comprehensive rehabilitation is required, at minimum, to meet the most frequently encountered physical and psychosocial needs of the patient. The services of physical rehabilitation encompass rehabilitation medicine, rehabilitation nursing, physical therapy, occupational therapy, speech and language pathology, psychology, and social work or case management. Older Joint Commission publications have discussed quality monitoring, goals, and evaluation for specific physical rehabilitation service departments (123). Possible “monitors” for physical rehabilitation services have included increase in self-care ADLs, mobility, reduction in pain, patient satisfaction with services overall and with specific aspects of services (e.g., satisfaction with fit and functioning of prosthetic and orthotic services); cognitive and emotional adaptation of the patient and family to disability; improvement in communication skills; health maintenance; and reduction or prevention of preventable complications commonly seen in the impairment group. Such goals and indicators resemble the objectives and goals in PE systems in medical rehabilitation. A difference is that PE goals were typically for the entire program or a broad diagnostic group rather than for a clinically well-defined group of patients. Interdisciplinary team objectives are preferable to departmental goals where such a team is routinely critical to achievement of outcomes for the patient. In comprehensive rehabilitation, the attainment of functional goals for the patient typically involves such a team.

## **GUIDELINES AND EVIDENCE-BASED PRACTICE**

Changes in the health care environment have resulted in increasingly systematic and critical examination of routine treatment throughout health care. No longer are health care

consumers and payers content to make decisions on the basis of word-of-mouth reputation alone. Rather, quality and outcomes data are increasingly checked, and each episode of care is subject to both cost-containment policies and usually implicit standards of “best practice.” *Clinical practice guidelines*—also called *practice guidelines* or merely *guidelines*—explicate best care practices.

Typically, practice guidelines are detailed descriptions of how different types of patients should be evaluated and treated in different circumstances. They aim to define standard, quality clinical practice for commonly seen and well-understood patient problems. Because they define care quality, guideline development is intrinsic to performance monitoring and actual improvement in clinical practice. Guidelines should include enough detail to specify ordinarily appropriate decisions and processes. They typically involve a sequence of initial measures, alternative clinical processes, at least some decision rules, and subsequent assessment of patient responsiveness or clinical outcome. Current practice guidelines typically synthesize scientific evidence with knowledge of normal practice as well as information on patient values. Well-developed guidelines are more applicable to clinical practice than review articles (124), and they are particularly useful for clinical education.

There is a growing subset of practice guidelines called integrative care pathways (ICPs) (125). Originally termed anticipated recovery pathways, ICPs are often referred to as multidisciplinary pathways of care, care protocols, care maps, or collaborative-, coordinated-, or critical-care pathways. As with any guideline, ICPs aim to have the right people provide the right care in the right sequence and in the right place to achieve the right outcomes. ICPs are designed to help clinicians and facilities reach or exceed existing quality standards and decrease unwanted practice variation (126). ICPs involve tracking of deviations (termed variances) from the expected care plan or outcomes. Information obtained from these variances is used to alter care plans or adjust outcome expectations so that future patients may experience better and more predictable results (127,128).

### Evidence and Bases for Guidelines

Guidelines have traditionally been based on knowledge of usual practice, and their implementation has focused on identification of practice variations. Increasingly, guidelines are based on systematic evidence review methods (7). The measures and criteria employed in guidelines and quality and outcomes monitoring systems need to be based on best-available evidence. Medical rehabilitation, like all health care disciplines, needs to strive to base its practices on stronger evidence than is provided by custom or observational data. Criteria for such evidence have become increasingly well-defined as the movement for evidence-based medicine and EBP has grown. It is now possible to systematically grade the strength of available evidence for the care received by rehabilitation patients (53). Systematic reviews and meta-analyses (see <http://www.cebm.net/>) provide the essential basis for quality monitoring and improvement. Chapter 80 explains EBP in rehabilitation more fully.

High-quality guidelines are developed using increasingly standardized, formal methods of synthesizing information from expert judgment as well as from research studies (129). The combination of systematic evidence review and expert consensus can result in an authoritative and reliable guideline that can give clinicians greater confidence in making treatment decisions (130). Randomized clinical trials (RCTs) are the most widely accepted standard for evaluation of treatments. When strong evidence of treatment effectiveness is synthesized into guidelines, clinical applicability is clear (27,100,121).

Direct evidence for the effectiveness of many types of rehabilitative care is limited, but relevant RCTs and a larger number of lesser controlled studies do exist, with the strength of evidence varying across diagnostic groups and interventions (53). Synthesizing evidence on the effectiveness of rehabilitation is not easy. Rehabilitation is multifaceted and involves an array of medical and nursing interventions as well as therapies that work through the activity of the person, such as physical therapy, occupational therapy, and speech/language pathology. Strong evidence is unlikely to be available for this entire array of interventions. Nonetheless, interventions based on learning and physical conditioning surely “work,” as do many environmental modifications, prostheses, orthoses, nursing interventions, and pharmaceutical interventions from general medical care. Guidelines can be written that integrate evidence and experiences from many therapies and methods. Adherence to such guidelines has been associated with greater functional gain and patient satisfaction (131,132). In addition, carefully developed evidence-based guidelines provide a good basis for quality-outcomes monitoring.

### Grading Strength of Recommendations to Strength of Evidence

Strength of recommendations should be graded according to the strength of evidence. Table 12-1 presents the most widely used method for connecting level of evidence to strength of recommendation. The method is used by several medical societies and evidence review organizations. Though often overlooked, the point is critical to rational and successful implementation of evidence-based guidelines.

**TABLE 12.1** Proportioning Strength of Recommendation to Strength of Evidence

Level	Recommendation	Evidence
A	Should be done	Established as effective: two consistent class I (rigorously controlled) studies
B	Should be considered	Probably effective: one class I study or two consistent class II (e.g., cohort) studies
C	May be considered	Possibly effective: class III studies, e.g., natural history controls or own control

Source: (7).

When evidence is unequivocal, and the human outcomes involved are highly important, the treatment or procedure in question should be considered to be a standard. Compliance should be monitored. But evidence in rehabilitation typically is not unequivocal (53). Recommendations based on weak evidence are more likely to be overturned by future research, and there are likely to be exceptions that are currently unknown. When evidence for a clinical procedure is weak or merely suggestive, it is difficult to find a rational justification for policies requiring all clinicians to do it. At the same time, even weak evidence may be the best available, and such evidence should be seriously considered and presented as a treatment option. Consideration of best-but-weak evidence could be a quality indicator, but rigid adherence, exaggerating the strength of knowledge, would not have a scientific basis. The importance of the procedure, patient preferences, and the human outcomes involved—whether transient discomfort or total disablement hang in the balance—also affect the strength of recommendation.

### Guidelines for Common Conditions

Initially led by the IOM and the Agency for Health Care Policy and Research (now the Agency for Health Care Quality and Research), work to develop clinical practice guidelines and clinical paths has spread throughout the health care industry (100,125). Thousands of clinical practice guidelines have been developed. An outstanding source for these is the National Guidelines Clearinghouse (<http://www.guideline.gov/>). At the time of this writing, the site lists 102 guidelines relevant to medical rehabilitation (excluding psychiatric and substance use rehabilitation, purely preventive guidelines, nonreconstructive plastic surgery and dental problems, and developmental learning disorders). Some of the more rehabilitation-relevant guidelines include those for

- Poststroke rehabilitation (133)
- Several pain syndromes, including low back problems
- Medical complications following SCI, including depression, autonomic dysreflexia, and prevention of thromboembolism
- Brain injuries (an authoritative National Institutes of Health review, but so general it should hardly be called a guideline)
- Cardiac rehabilitation (134)
- Treatment of lower-limb osteoarthritis, with rehabilitative implications (as with other guidelines, they vary in quality and use (135))
- Deep vein thrombosis
- Treatment of depression in primary care
- Treatment of pressure ulcers (136) and their prediction and prevention (137)
- Acute and chronic management of urinary incontinence (138)
- Fall prevention
- Exercise and strength training
- Several other neurological and neuromusculoskeletal conditions

More information on ICPs and examples of existing tools is available on the National Library for Health Web site (<http://www.library.nhs.uk/pathways/>). There is also a journal explicitly devoted to exploring all aspects of ICPs: the *Journal*

*of Integrated Care Pathways*, published by the Royal Society of Medicine (<http://www.rsmppress.co.uk/jicp.htm>). Other sources also provide information on guidelines, care pathways, and related forms for medical rehabilitation (139,140).

### Implementation and Impact of Guidelines on Practice

Research on the impact of guidelines on clinical practice and outcomes is emerging. Initial hopes that guidelines would greatly improve the quality of medical care, improve health outcomes, and constrain the growth of medical care expenditures as a whole have been dashed. Adherence to guidelines has often been limited, and many guidelines are little used after publication. Nonetheless, some well-developed guidelines have been widely accepted. Guidelines have repeatedly been associated with small-to-moderate improvements in care processes (141,142). Effects on health outcomes have been less studied and are less clear. As examples, researchers have documented 30% reduction in adverse events from antibiotics, a 27% decline in mortality, and decreased costs when using computer programs that help physicians choose antibiotic treatment (143). A detailed treatment protocol for mechanical ventilation can reduce unwarranted variations from good practice and substantially improve survival (144). Randomized trials have shown that, when combined with feedback on performance and education by respected peers, practice guidelines can improve medical care processes and outcomes (130); however, success varies among settings, procedures, and health conditions.

Developing and implementing guidelines for stroke rehabilitation are particularly difficult, given the multiplicity of presenting problems and consequent complexity of needed treatment. Clinical pathways have been shown to reduce LOS and complications in acute stroke care, but the results from stroke rehabilitation are more equivocal (145). Adherence to stroke rehabilitation guidelines was associated with greater functional recovery (146) and patient satisfaction (132) in a Veterans' Administration study. Conversely, a randomized trial comparing a clinical pathway with traditional stroke-team rehabilitation (147) found no advantage in either cost or patient gains; it even decreased patient satisfaction. A possible explanation is that specialized stroke-team rehabilitation is already highly developed and consistent, and it would be difficult to write guidelines that improve functional gain, complication rates, patient satisfaction, and LOS attained by existing experienced and coordinated rehabilitation teams. Similarly, guidelines designed to explicate only basic care requirements likely define what virtually everyone is already doing.

Research on guidelines for depression deserves further mention, not only because persons with disability exhibit depressive symptomatology more frequently than the general population but also because research on their implementation is instructive. A substantial body of research has elucidated effective methods for recognizing depression and improving its treatment in ordinary care settings (148). Research has shown that clinical information and education are necessary

but insufficient. To achieve levels of treatment and outcome recommended by the guideline, patients too must be educated and encouraged. “QI efforts that focus resources on improving systems of care and the active participation of patients offer the best evidence of improved patient outcomes” (149). Knowledge of organizational tactics and factors enhances the likelihood of successful implementation of guidelines (150).

Computer decision support systems have similarly demonstrated improvements in clinical practices (151). Using a touch screen, for instance, patients or staff can complete a questionnaire, and responses can be processed against evidence-based guidelines at the time of the clinical encounter. Care suggestions, targeted to the patient’s history; comorbid conditions; and current symptoms can also be provided. Reminder and suggestion systems have only begun to be developed, but both patients and health care practitioners have been generally satisfied with them (152).

Cost is a constant concern in health policy and in terms of actual rehabilitative care. Implementation of cost-conscious guidelines has been reported to save substantial sums in certain circumstances (145,153). However, methods of ethically incorporating costs into guidelines are not yet well developed or widely accepted (154). The cost-effectiveness of alternative approaches to assuring and improving QOL, including EBP, QI, and patient partnerships, needs to be examined (155). Even with all these shortcomings, we can expect the development and use of clinical guidelines to increase in the future.

The ultimate goal of introducing clinical guidelines and paths is to establish the means for a multidisciplinary team to provide coordinated, timely, outcome-focused, and patient-centered care while using the minimum necessary resources (125,156). Standardized protocols facilitate this process by revealing detours from established best practice, identifying patients who are not responding as expected, and generating data sources to stimulate research (157,158). Furthermore, guidelines can be educational for new team members.

Multifaceted approaches to guideline implementation, involving provision of written information, talks with local consensus discussions, and individualized contact by colleagues (academic detailing), appear to be most effective in dissemination (141). Guidelines and attempts to implement them should be pilot tested and built into normal, ongoing channels for improving care. Obstacles to implementation vary across organizations, so a preliminary diagnosis of the organization itself is logically needed to identify barriers and optimal implementation strategies—a topic on which more research is needed.

### **Critique of EBP and Guidelines**

Evidence-based guidelines are now widely accepted by clinical professionals and policy makers as essential bases for clinical practice. Expert, best-practice guidelines can improve clinical performance and serve as a tool for clinicians and a source of information for patients. Evidence-based guidelines are a necessary and potentially powerful tool for accountability and QI, as well as to achieve effective and efficient care, though limitations are becoming clearer (159,160).

Guidelines can be rigid, based on the assumption that one single method of care is best when several approaches may be effective. Proliferation of forms and applicability to varying local circumstances remain concerns. Patient acceptance has not been considered in development of some guidelines, and though patient involvement may be recommended, specifics of how this is to occur are often not given. Guidelines need to be tested to evaluate their use in practice and whether they actually improve clinical processes and patient outcomes. They will also need recurrent revision.

While the feasibility of guidelines in rehabilitation—at least for certain better understood problems—has been established, most existing guidelines focus on medical/nursing aspects of care. Many conditions and clinical practices in rehabilitation are not covered by guidelines or by direct efficacy research. However, practice guidelines and care paths can be beneficial in chronic conditions wherein the focus is not on curing so much as maximizing functional independence and QOL (125,161–164).

Guidelines themselves vary in their quality. Some are well based on evidence, while others are based largely on expert opinion. The few guidelines that have been produced for rehabilitation involve substantial expert opinion (e.g., for stroke rehabilitation) or target highly specific conditions (e.g., prophylaxis of deep vein thrombosis). Criteria now exist for appraisal of the quality of clinical practice guidelines (165,166). Guidelines need to be developed to the point that they are useful for professional and patient education and should be sufficiently detailed and clear that one can objectively evaluate the degree to which patients have received the needed care and experience the expected health benefits.

## **INFORMATION SYSTEMS FOR PERFORMANCE MONITORING**

Until recently, “health care delivery has been relatively untouched by the revolution in information technology that has been transforming nearly every other aspect of society” (1, p. 15). The mass of information on personal health collected in encounters with health care professionals is a great potential resource for improved quality of care, but that information is dispersed in poorly organized, sometimes illegible, paper records at a variety of sites, with fears of security breaches inhibiting access to the information needed to understand and manage patients with chronic illnesses and disabilities. Systematic improvement of care, quality, and outcomes in health care involves attention to information flow, the medical record, and the clinical data system. A sophisticated system for data retrieval, analysis, and reporting is required to convey information to clinicians in a useful, timely way, improving quality and outcomes.

### **Data System Structure: Inputs, Processes, and Outcomes**

Performance monitoring systems involve measures of three types—inputs, processes, and outcomes. Figure 12-4 shows

**FIGURE 12-4.** Simplified schemata for rehabilitation PE and outcomes management.

two schemata for outcomes-oriented monitoring systems. In traditional PE systems in medical rehabilitation, the emphasis has been on outcomes, and the process box is sparse. There is no explicit theory or guideline to determine what aspects of intervention should be measured, so that rehabilitative processes are treated virtually as a black box (at the top of the figure). The approach has been useful to characterize patient gains associated with comprehensive medical rehabilitation programs, where processes are so multiple and complex their complete explication would appear to be an intractable task. Many current data systems in medical rehabilitation are like this, including data systems for the PPS based in the IRF-PAI. A minimal ability to analyze the effect of general factors such as intensity of treatment, primary impairment, payer, and demographic factors for somewhat similar patient groups (e.g., FRGs or CMGs) may be provided. However, the limitations of this model have been increasingly recognized (13,51,112,167,168). When needed processes are not stipulated and measured in the data system, it is extremely difficult to identify what might be done to improve the appropriateness or outcomes of care.

More sophisticated data systems—tied to the actual process of rehabilitation planning and treatment provision—have been attempted in rehabilitation (79,80,169). As displayed at the bottom of Figure 12-4, treatment objectives and progress are represented by arrows. While some functional and medical measures may be constant across all patients, others vary to permit needed individualization. Treatment objectives are chosen to fit the priority needs of the individual (79,80). Ongoing patient reassessment is part of quality rehabilitation ((20), Joint

Commission Standard 6.2), so a more adequate data system incorporates change in patient functioning and treatment objectives. Whether medical and functional goals have been attained (and possible reasons if not) is determined in patient follow-up. Requirements for attainment of a productive, independent lifestyle are evaluated. Given the importance of discharge planning to quality rehabilitation ((20), tx.6.1.1), environmental, family, and other requirements for discharge to a maximally independent living arrangement need to be evaluated.

The provision of rehabilitation services should be guided by an interdisciplinary plan ((20), tx.6.3). When the objectives in a performance monitoring system are based on actual rehabilitation plans for individuals, it is a true *clinical outcomes management data system*. With such a system, the team can be provided with specific and potentially valuable feedback on their ability to choose objectives, implement effective interventions, and attain outcomes for individuals served.

### Information System Design and Integration

A fully automated medical record is not needed to achieve QI (1). Automated order entry systems can reduce errors in prescription and delivery of medications (170). Reminder systems have recurrently been shown to improve compliance with clinical practice guidelines (171). Although current examples are few and limited to specific structured problems, computer-assisted diagnosis and management promise to improve quality in the future (1,131).

Information has traditionally been entered in free form, sometimes illegible notes, into paper medical records.

If entered into computers, new natural language search engines make retrieval of information from free text notes possible. Even so, natural language recording yields results of limited reliability, given individual variations in style and completeness of recording.

Information systems, whether on computer or paper, can present clinicians with standardized, relevant considerations and information to assist them in their diagnosis and treatment decisions and in monitoring response to treatment. Common evaluation and intervention processes can be presented in a format (e.g., prompts or a flow sheet) that reminds clinicians of standard best practices and simultaneously facilitates recording of whether these are done. Additional screens or pages can facilitate standardized measurement of patient responsiveness. The importance, appropriateness, simplicity, and *transparency* (understandability) of items presented to clinicians are critical to a usable clinical data system. While structured input is needed for systematic QI and outcomes monitoring, free text notes are still required to record individual variations and for the numerous clinical situations for which validated, structured guidelines do not exist.

The idea of integrating information systems is hardly new, but it is still common for health care organizations to have multiple poorly integrated recording systems. Clinical data may be recorded in paper, medical records, professional files, or in pharmacy and other departmental computers. Billing records may be in an entirely separate system. The integration of clinical, financial, case management, QI, and outcomes data increases the potential use of these systems (75,79).

Computerization assists QI by increasing the amount of data available but does not in itself provide more relevant or useful information. A mass of information can enhance decision making, but it can also confuse the process. The bottleneck may not lie in collection of data but in analyzing

data and synthesizing it with knowledge, based on evidence and clinical experience, to highlight meaning. One could argue that the performance monitoring literature has concentrated too much on measurement and too little on how to use the data. Routine performance reports give rise to hypotheses about problems in the program or why outcomes are or are not attained. In-depth analyses are needed to test hypotheses about alternative explanations about *why* performance is better or worse than expected. The information system must facilitate professional statistical investigation and interpretation.

Information systems are justified not by single use but by their multiplicity of uses. The following sections will discuss clinical and then management uses.

### Clinical Reporting and Uses

Reports of functional gains by patients have been used in rehabilitation for decades, not only to evaluate the rehabilitation program as a whole and to assist in QI but also to organize communication and set goals in the rehabilitation team conference (172). Patient functioning and improvement are key indicators in utilization review and assessment of readiness for discharge in rehabilitation (37,172). Data on functional history and gains have also been used to assist case managers by predicting outcomes.

Rehabilitation information systems can produce informative, graphic displays of individual patient progress used in team conference, case management, and reports to referral sources or payers. Figure 12-5 presents an example of such a report (63,172). Functional tasks are ordered by difficulty: the easiest, first-to-recover activities are presented to the left with more difficult activities to the right. The case displayed is a possible discharge candidate. Team discussion of the patient's functioning, lifestyle preferences, special needs, and family

**FIGURE 12-5.** Status and goal profile of a possible discharge candidate. (From Silverstein B, Kilgore KM, Fisher WP. Implementing patient tracking systems and using functional assessment scales. In: Harvey RF, ed. *Center for Rehabilitation Outcome Analysis*. Vol 1. Wheaton, IL: Marianjoy Rehabilitation Center; 1989. Monograph Series on Issues and Methods in Outcome Analysis, with permission.)

support is needed for quality rehabilitative management and a safe, high-quality community placement (173).

Well-designed reports tell us whether desired, attainable results are in fact routinely attained and whether interventions are being applied to patients who are most likely to benefit from them. There are several common, avoidable traps in interpretation of clinical outcomes data. First is the common tendency to assume a massive effect of treatments. Rehabilitative interventions will tend to lessen complications and augment healing and adjustment, but quick cures are not ordinarily expected. A second common error is assuming that improvement is due entirely to rehabilitation. Improvement can be due also to natural healing and family and environmental processes that can occur at home. Conversely, failure to improve may not reflect provision of inadequate treatment. Reports need to incorporate sophisticated severity adjustment to identify patients with anomalously poor outcomes. Even then, detailed clinical data are needed to judge whether failure to improve is associated with provision of substandard care (81).

### Case Management Databases and Their Uses

Difficulties in use of traditional routine clinical monitoring data systems are not entirely due to technical deficiencies, although these exist. When there is a concrete motive (e.g., a financial motive), clinical data systems are used. Managed care organizations, for instance, have developed their own databases to track the appropriateness of medical care, including medical rehabilitation. These databases concentrate on financial factors but increasingly include detailed clinical data. If the case management agency does not like the care or outcomes of patients sent to a rehabilitation provider, it does not send new cases to that provider. Only a minority of expensive cases are managed with the use of such databases, but for this minority, the external party's data system is essentially the operational outcomes management database. These case management systems are typically proprietary, but their adequacy and impact on patient care and outcomes are of public interest.

### Management Reporting and Uses

Management reports are the routine product of performance monitoring systems. Patient progress, indicators of clinical outcomes and processes, goal attainment rates, efficiency, case-load, service intensity or frequency, and trends are reported periodically. Reports may go to the governing board and staff as well as clinicians and managers. Both frontline staff and key decision makers should receive findings and use them. Performance reports should engage staff at all the levels of the organization involved in actually implementing possible improvements based on the findings. Data on patient progress or outcomes may also be formatted for release to purchasers of services and the public (18,69,70).

### Managing Length of Stay and Cost-Effectiveness

Management of LOS and readiness for discharge is critical in rehabilitation facilities in the United States and is a major use of clinical information systems. Additional uses include

marketing (174), refined profitability analyses, planning, accreditation, and estimation of patient acuity for determination of staffing requirements (71,72,75,79–91). LOS, however, is not an indicator of quality. Shortening LOS in rehabilitation has been accompanied by an increase in the frequency of rehospitalization after discharge (175). Discharges of hip fracture patients from acute hospitals with active clinical issues (e.g., temperature, blood pressure, other vital signs) or with new impairments have been associated with increased rates of rehospitalization and mortality, and patients who develop new impairments have worse functional mobility (176). Information systems need to present data on patient readiness for discharge.

Interpretation of cost-effectiveness data requires understanding of basic relationships. More severe cases tend to receive and require longer care (25,61). While outcomes *per se* often have little relation to effort or even an inverse one, improvement in medical rehabilitation hospitals is and should be probabilistically related to LOS (25,60). Strategies for cost-benefit and cost-effectiveness analysis in rehabilitation are presented in other works (177).

### Outcomes-Focused Quality Improvement

Given the lack of evidence for a single best way to deliver rehabilitative care, it makes sense to monitor functional outcomes, giving programs leeway in how they produce these outcomes. Shaughnessy et al. have shown that outcomes-based QI can substantially improve patient outcomes (178). In a study of over 300,000 patients receiving services from home health agencies, outcomes-based QI reduced rehospitalization for targeted conditions by 22% to 26% over 3- to 4-year demonstration projects, compared to a 1% reduction in matched non-outcomes-based QI agencies. The risk-adjusted rates of improvement in outcomes-based QI target outcomes measures of health status averaged 5% to 7% per year in demonstration trials and were significantly greater than analogous improvement rates for nontarget comparison outcomes, which averaged about 1% per year. There is no reason why outcomes-focused approaches should not work for other forms of rehabilitation as well.

In general, when a program or patient group has higher or lower outcomes than projected, this by itself does not constitute evidence for high or low quality or effectiveness of care (87). Although FRGs/CMGs can be modified to predict up to 63% of the variance of discharge FIM scores, current severity-adjustment methods typically predict only a minority of the variance of patient *gains*, so that much is left unexplained (87,179). Outcomes after rehabilitation are due to many factors beyond the control of even high-quality care. As a consequence, a discrepancy between expected and actual outcomes is validly usable (only) *as a first-stage screen*—an indicator of a possible problem or opportunity to improve operations (Fig. 12-6). The discrepancy indicates that further investigation is needed.

*Second-stage screens or investigations* are required to determine whether there are deviations in care processes or whether

**FIGURE 12-6.** The outcomes-focused QI cycle.

differences in outcomes reflect unmeasured patient or environmental factors. Many studies show that appropriate use of outcomes data to improve clinical processes “virtually always requires detailed clinical data” (119, p. 868). Peer review of charts may be employed to determine reasons for deviations but are expensive. Chart review may focus on patients whose outcomes are particularly discrepant, but ad hoc methods may fail to detect remediable problems.

A system for in-depth analysis and review of detailed clinical data, accessing well-developed guidelines and evidence regarding desirable clinical procedures, is needed to confirm whether a discrepancy in process or outcomes implies actual deficiencies or not. The difficult process of determining reasons for suboptimal outcomes should not be left to harried local QI committees or part-time PE staff without well-developed tools to assist and guide their efforts. Objective review criteria that connect outcomes to process deviations are feasible and have begun to be developed for home health services (144) and stroke rehabilitation (132,146). Perhaps the greatest technical problem with current approaches to QI in rehabilitation is that the evidence-based guidelines and methods of operationalizing them in second-stage analyses have not been developed and validated.

When a problem or opportunity for improvement in care processes is identified, the quality task force should direct effort toward solving the problem. In this *third stage*, detailed

practical planning should occur, followed by implementation and change in care processes. Continued monitoring will reveal the impact on patient outcomes. In principle, performance improvement efforts can and should have the capacity to focus on several points in the causal chain connecting clinical processes to intermediate and long-term outcomes. QI analyses, for instance, can identify patients who experience variances in care processes and determine if their severity-adjusted outcomes are in fact below expectation. If so, action is indicated. Evidence-based clinical guidelines and methods of operationalizing them are needed to improve performance, whether the initial examination focuses on processes or outcomes.

## OTHER APPROACHES TO PERFORMANCE IMPROVEMENT

### Professional Education and Development

Education of professional and other staff is an essential component of QA and QI. The quality of care provided in practice is dependent on professionals’ pride, ownership, and self-regulation. In appropriate environments, clinical professionals will strive toward improved competence and improved practice. These assumptions underlie current professional licensure, testing, and continuing medical education, although classic continuing medical education approaches involving courses, provision of written materials, and conferences have demonstrated only limited effectiveness (160,180). A variety of more interactive, realistic, and timely educational methods may prove to be more effective. Educational outreach and personally tailored approaches are promising; small group learning and physician peer review are also useful (160). Bottom-up approaches, involving clinical education and formation of groups of clinicians charged with improving quality, have been shown to improve clinical practice (160). A variety of new and revised educational techniques will be needed to provide the skills required to enhance the quality of health care, including skills in interpretation and applications of evidence and guidelines, using decision support systems, and communication with patients as full partners in decision making (1).

### Patient-Centered Approaches

Although details may vary, patient-centeredness and assessment of quality from a patient’s perspective are essential components of quality health care (1). We will primarily consider the monitoring of patient satisfaction, a clearly practical matter, and then comment on broader issues of patient involvement or empowerment.

### Patient Satisfaction

The monitoring of patient satisfaction has deservedly become a standard part of performance monitoring in health care. Patient satisfaction is evaluated as both a process and an outcome. There are persuasive practical reasons for organizations to have

a strong emphasis on patient satisfaction. Patient satisfaction is measurable at a modest cost (181). A facility's reputation is largely based on satisfied clients. Marketing is enhanced by high customer satisfaction, both by word of mouth and presentation of satisfaction information. Patient perceptions of quality have been found to be robustly correlated with hospital profitability (182). Increased patient satisfaction has been associated with decreased risk of malpractice suits (183).

Measuring patient satisfaction helps both clinicians and administrators understand patients' care experiences. Patient satisfaction assessment can identify problematic processes. Dissatisfaction rates are much higher in facilities that misrepresent the services they offer (27,181,184). Satisfied patients tend to be more compliant to treatment recommendations (185).

Well-validated, reliable questionnaires, with available normative data, are available for assessment of patient satisfaction and should be used. Multipoint rating scales have become standard (e.g., ratings from "very poor" to "very good" or "excellent"). Valid satisfaction questionnaires avoid bias, giving customers freedom to complain if they feel like it. The point is to get information rather than to manipulate a vote of approval. Mail provides more anonymous results than phone calls and at lower cost, but low-response rates can be a problem. Patient satisfaction questionnaires have been published for general medical settings (186) and for inpatient (187) and outpatient (188) rehabilitation programs (23). Many large group health organizations have adopted standard formats for assessment of patient satisfaction based on Ware's research (189). Third-party firms provide standard satisfaction monitoring systems, including reports of comparative data across settings. Reports are needed for different types of patients and should target different actionable areas of care.

Patient satisfaction measures have limitations and need to be presented to staff in a positive light. Care issues are often viewed positively. Patients tend to express high satisfaction with medical rehabilitation services. "The most consistent finding is that the characteristics of providers or organizations that result in more 'personal' care are associated with higher levels of satisfaction" in medical settings (181), while patient satisfaction is poorly or inconsistently related to technical effectiveness and professional standards. Satisfaction measures often elicit comments about food, temperature, billing hassles, and other facility and personal services. Billing and cost issues typically receive ratings that are distinct from care issues and should be summed and reported separately from care issues. Administrative journals provide advice on how to interpret and use patient satisfaction data (190).

### Patient Involvement

Increased patient involvement or empowerment has been propounded as a way to improve the quality of rehabilitation programs. CARF accreditation particularly emphasizes and even requires patient involvement (18), and Joint Commission standards now also state that the rehabilitation plan is "developed by qualified professionals, in conjunction with the patients

and/or his or her family, social network or support system" ((20), tx.6.3). Patient autonomy is a basic value, and involving "consumers" is seen as essential to enabling them to receive the individualized care they desire. Patients' valuation of outcomes may differ from those of professionals, and individual patients have differing functional needs. "Consumers" of rehabilitative services may choose cognitive and communicative abilities over physical abilities (191), although conventional outcome measures weight them equally or even give greater weight to physical outcomes. The significance of the same disability can vary among patients (27,81,192), who have differing lifestyles and live in differing cultures.

Differing methods of empowering or involving patients have been employed, including satisfaction surveys, complaint procedures, communication training for professionals, surveys of patient needs, and enhanced provision of educational information. One of the few studies on the topic has reported encouraging results of a system involving a patient care notebook in a rehabilitation setting (193). Patient, family, and team are all involved in the notebook, which also educates the patient in self-care and is used as a resource when the patient goes home.

Many studies have been done on physician-patient communication, and reviews show that various indicators of sensitive caring communication and patient-centeredness lead to greater patient satisfaction and even to better compliance with prescribed treatment (194). While most patients want to receive information on their condition and treatment alternatives, many do not want to make key decisions regarding necessary treatment; seriously ill patients in particular may not want to take responsibility for management of their disease (195).

After decades of simplistic advocacy of patient involvement and professional suspicion of patient opinions, new conceptualizations of patient-centered care have been propounded. "Dialog-centered care," based on a clearer definition of the rights and responsibilities in communicative process between clinicians and patients, is among the most promising of these (160). Research is needed to clarify methods and circumstances for appropriately involving patients in such a way that satisfaction and outcomes are improved.

### Clinical Practice Improvement

Systematic "clinical practice improvement" (CPI) has led to insights and improved care processes in a number of areas of medical care (196,197). Developed by Dr. Susan Horn, CPI is a data-driven "bottom-up" approach involving collection of data on processes of care, relevant outcomes, and patient characteristics, including indicators of severity. Clinicians who choose different practices from those in the protocol are given the opportunity to present their reasoning to the CPI team so that the protocol can be modified or consensus can be reached. The goal of the process is to enable clinicians to improve severity-adjusted outcomes within cost limits or to maintain relevant outcomes while decreasing costs. Sophisticated multivariate statistics are used to statistically control for factors that confound process-outcome relationships for selected subsets

of patients. Process variations are lessened through ongoing feedback from statistical analyses, discussion, and consensus.

Proponents of CPI argue that clinical practice guidelines are often based on a consensus of experts, and what scientific evidence is available is often limited or based on selected patient groups and programs that vary from those seen in practice. CPI studies have identified actionable factors that associated with severity-adjusted outcomes (e.g., earlier admission of stroke patients to rehabilitation) (198). The validity of CPI depends on the accuracy of the statistical adjusters employed—an uncertain matter. Compared to typical RCTs, CPI has less internal validity but greater external validity, that is, greater generalization to practice.

## PUBLIC ACCOUNTABILITY AND HEALTH SYSTEMS ISSUES

Trends in health care as a whole impact and even overshadow rehabilitation, which is a relatively small part of the total health care “system.” Current payment policies in the United States are complex and contradictory and may provide no incentive for improving the quality or true efficiency of care (1). Rehabilitation may face a “market” that disempowers its “customers”—persons with disability (199).

### Changes in the Health Care Industry

Cost control mechanisms, including various managed care mechanisms, risk-sharing arrangements, and Medicare’s PPS, have heightened concern about the quality of rehabilitative care. Although reports on the quality of care have not always shown that managed care arrangements provide worse care to persons with disabilities and chronic conditions, many of these firms have incentives to do so, as these patients cost much more to care for than the average patient (31). Under capitated payment arrangements and disabled and chronically ill individuals are money losers, so the incentive is not to enroll such individuals, to treat them as inexpensively as possible, and hope that limited services will induce them to sign up for alternatives. Severely disabled individuals lose their private insurance and shift to Medicaid or Medicare. The disabled individuals affected may be poor and limited in mobility, and some cannot communicate articulately and so cannot advocate effectively for themselves. Organizations may decline to participate in studies of rehabilitation quality and outcomes. Mortality and apparently also rehospitalization rates following inpatient rehabilitation have increased in recent years (200). In sum, rehabilitation is vulnerable to adverse pressure in the changing health care system in the United States, and quality of rehabilitative care is or should be a public issue as well as a professional one.

### Public Reporting of Performance

Fears regarding simplistic misinterpretation of quality and outcomes data are still with us, leading to restrictions on access to and use of data. The data in rehabilitation clinical

information systems, like that in other medical information systems, have been the private property of the facility. Consumers and the public, however, are major stakeholders to the rehabilitation process and have a valid claim to deidentified performance information (i.e., information that does not identify any individual patient). Medicare now releases severity-adjusted data on quality of care in nursing homes and home health (see <http://www.medicare.gov/>). The Center for Medicare and Medicare Services may release similar reports on outcomes in inpatient rehabilitation.

Payers and large health care institutions have developed methods of profiling the cost and case mix of physicians and facilities, but little has been published regarding the reliability or validity of these systems. Because nonspecialist physicians may encounter only a small number of patients with a specific disease, physician profiles could easily be unreliable, and individual physicians could game the system by avoiding just a few severe, high-cost, or poorly adherent patients (201).

### Health Plan Report Cards

Consumer Assessment of Health Providers and Systems (CAHPS) was developed with funding from the Agency for Health Care Quality and Research to evaluate quality of care from the viewpoint of consumers or patients. The CAHPS has evolved to a family of standardized surveys on multiple types of care, and reports from the CAHPS are widely disseminated (<http://www.cahps.ahrq.gov/default.asp>). CAHPS’ surveys on disability and rehabilitation have not yet been developed.

The National Committee on Quality Assurance (NCQA) (see <http://web.ncqa.org/>) was formed to address quality issues among managed health care plans. Without objective measures and credible data, competition between such plans is possible only on the basis of cost. The NCQA accredits health plans, and its Health Plan Employer Data and Information Set (HEDIS) is now used by the majority of health care plans in the United States to provide data on quality processes, professional resources, and outcomes (see <http://www.ncqa.org/>). The number of HEDIS quality indicators has increased over time too. The current (2008) version has expanded to include 80 indicators sets, including indicators of effectiveness, access/availability, satisfaction, plan stability, intensity of care utilization, and structural descriptors. A few outcome indicators or surveys are specified (e.g., the Medicare Health Outcome Survey), but most are process indicators. Quality indicators are specified for a number of chronic conditions (e.g., diabetes, cholesterol management after acute cardiovascular events) and for disease management programs but not for the neurological, traumatic, or orthopedic conditions commonly seen in inpatient rehabilitation hospitals. HEDIS data are compiled into a national database, and report cards are issued on health plans.

Whether HEDIS is measuring the most important factors is controversial. HEDIS quality indicator sets, however, continue to evolve, expand, and improve. Case studies attest to the use of the database in organizational QI efforts (<http://www.qualityprofiles.org/>). A broader issue is that accreditation

and much reporting are voluntary. Health management organizations (HMOs) with lower quality-of-care scores have tended to stop disclosing their quality data (202). In sum, adequate health plan report cards have not yet been developed for disability and rehabilitation, but CAHPS and HEDIS provide an essential basis for future progress.

### **Incorporating Wider System-of-Care Factors in Performance Monitoring**

The monitoring of the quality of the specific services provided can beg the question of whether a different type of service might provide superior benefits to patients and whether the person served has major unmet service needs. Although monitoring of current care processes is appropriate, performance improvement systems have greater potential use if they consider all interventions known to be effective for patients' problems, regardless of whether they are currently offered by the program. Studies of quality in acute care hospitals have reported that errors of omission (e.g., a physician not detecting a major diagnostic problem) were more common than errors of commission (not providing the correct treatment for the diagnosis) (29). Errors of omission of needed rehabilitative treatments may be frequent as well, especially given today's cost and LOS constraints. The results of inpatient rehabilitation, for example, will be compromised if quality follow-up care is not provided. A wider consideration of patient needs might lead to QI efforts that address patient referral, adding or changing service mix, and education of payers regarding service needs. Patients, their families, and disability advocates can be influential allies in such education.

### **Cost and Value**

Awareness of the critical importance of cost has spread throughout health care, including rehabilitation. Even in the midst of pressures, however, it would be naïve to believe that cost is the only issue: the issue is the balance of cost to benefits or, in more general terms, value (31).

Interventions that are likely to produce small improvements in functioning of patients with severe chronic conditions are commonly available, but are these improvements—and hence, the interventions—worth the money? Systematic research is needed to provide evidence regarding the value of various rehabilitative interventions, bearing in mind that this value may vary depending on context. CARF accreditation regulations have touched on the issue. They have addressed the need for rehabilitation programs to formulate feasible objectives, involving the patient in this process, and to communicate appropriate information regarding associated results to stakeholders (18,68). The agreement provides *prima facie* evidence that attaining the objective is probably of some worth to individuals involved, but it is difficult to summarize the value of attainment of such diverse individualized results to payers and policy makers. In any case, honest communication regarding patient benefits associated with rehabilitation, including objective data on goal attainment and evidence regarding treatment effectiveness, to major stakeholders remains essential

to promoting a reputation for quality care and for nurturing the resources needed to maintain that quality.

Rehabilitation managers today are charged to develop systems that place each individual in a care setting that optimizes both outcomes and cost containment. The ability to predict outcome and to tier rehabilitative care to the level needed for the individual's improvement is becoming a necessity. To assure that each patient is provided the most effective rehabilitative care, objective indicators need to be developed that specify the level, type, and dosages of rehabilitation that should be provided.

## **SUMMARY AND CONCLUSIONS**

The IOM has documented the “quality chasm” between care realistically possible and that actually provided (1). To cross the quality chasm, the IOM has proposed six objectives for 21st century health care systems: health care should be safe, effective, patient-centered, timely, efficient, and equitable. The current nonsystem of care for persons with disabilities in the United States does not often meet these objectives. Persons with disability frequently are unable to obtain needed items and services from their health insurance plans and “experience more problems than others with follow-up care, availability of specialists, getting to doctors, and obtaining help during off hours” (199). Few would contest the assertion that there is a chasm between the quality of rehabilitation possible and that commonly provided to patients with disabling conditions.

### **Strategies for Performance Improvement**

Health care quality monitoring and use of QA data have changed greatly since QA programs were originally established. The focus has shifted from identifying poor care toward identification of feasible improvements that will benefit the majority of patients with frequently encountered problems and the implementation of these improvements. Quality of care is now understood to be complex and multifaceted, and no aspect of the total system of care can be excluded from consideration if quality is truly to be improved.

More than a decade after their initial vogue, TQM and CQI remain theoretically attractive approaches (155). The emphasis on quality care, not as performance of a defined action or even sequence of defined steps but as processes organized around patient problems, remains persuasive, as does the emphasis on improving systems, improving cultures, and developing smooth transitions between systems. Rehabilitation will do well to learn from CQI and TQM efforts in health care more generally, including acute medical care, psychiatric care, geriatric medicine, home health care, and long-term care (99,144,203,204). Cooperation within specially trained multidisciplinary QI teams leads to improved quality in medical care (205). Multidisciplinary team approaches are also particularly valuable approaches to operational QI in rehabilitation.

At the same time, limitations of TQM/CQI have become evident. As Grol points out, “the current TQM approaches should be better adapted to the realities of health care. Links

to other approaches (e.g., professional development and external assessment) should be established. Physicians should be actively involved and occupy leadership roles, and the QI activities should be related to their needs and to patient-related problems more directly” (160, p. 2583).

Multiple approaches are needed to assure and improve the quality and effectiveness of rehabilitative care. Processes and short-term and long-term outcomes all need to be measured either continuously or in occasional focused studies to identify opportunities for performance improvement as well as to keep score. More broadly, improving the quality of care in practice requires “building bridges among professional pride, payer profit, and patient satisfaction” (160). Major stakeholders to the rehabilitation process—patients, families, referral sources, payers, government, and the public—need to be educated to promote the supportive partnerships necessary for provision of quality rehabilitative care.

To improve rehabilitative care systematically, EBP guidelines are critical. Without such guidelines, there is no standard by which quality of care can be evaluated and neither process nor outcomes monitoring has definite action implications. The development of practice guidelines in rehabilitation is difficult, given the breadth and complexity of rehabilitation, and their implementation and results in practice should be monitored and studied. Much work remains to be done to determine the most valuable rehabilitative care processes and to incorporate the needed tailoring of treatment objectives to patient values. Evidence-based guidelines will not be possible for all rehabilitation problems, but even with limited evidence (e.g., stroke rehabilitation), it is possible to develop useful recommendations.

Rehabilitation professionals have developed systems for monitoring general outcomes and patient satisfaction. In their day, these systems were steps forward, but the limited evidence basis of these systems—including the misidentification of functional gain with true evidence of treatment effectiveness, combined with limited transparency and public disclosure—inhibited their utility. Work is needed to develop full-featured performance information systems that monitor care processes and outcomes and provide information from controlled research to support the interpretation of data. Such information systems should enable clinical professionals and patients to make better decisions as well as provide reports to administrators, payers, and government. Developing and using the results of such systems to assure and improve the quality and outcomes of rehabilitation programs are a primary challenge to the field and its stakeholders.

PART

# **The Rehabilitation Team: Systems-Based Practice**

# Rehabilitation Team Function and Prescriptions, Referrals, and Order Writing

Patients undergoing comprehensive rehabilitation require the services of multiple health care providers who possess unique skills, training, and expertise that are employed for the full restoration of these patients' function and their optimal reintegration into all aspects of life. The competent physiatrist must be able to communicate in an optimal fashion with all these providers to meet the many needs of the patient. Prescriptions, referrals, and orders are basic tools by which the physiatrist may communicate the desired involvement of other rehabilitation or medical specialties in assessment, treatment planning, treatment delivery, provision of equipment, and fitting of adaptive devices. Medical specialties that are commonly involved with the rehabilitation patient include neurosurgery, neurology, geriatrics, primary care (including family practice, internal medicine, and pediatrics), psychiatry, urology, and orthopedics. Many other medical and surgical specialties are consulted as needed. Assessment, treatment planning, and therapy are often provided by rehabilitation clinicians specializing in occupational therapy, physical therapy, kinesiotherapy, prosthetics and orthotics, psychology and neuropsychology, recreational therapy, speech and language pathology, rehabilitation nursing, social work, dietary science, case management, and others (Fig. 13-1, Table 13-1) (1,2). Which professions are involved with a particular patient and the extent of those involvements are largely determined by the nature of the patient's deficits and the structure of the setting in which rehabilitation is being conducted. As indicated by an initial comprehensive physiatric assessment, the physiatrist requests the participation of other rehabilitation specialists for their assistance in determining the appropriate rehabilitation services and level of care, as well as for comprehensive rehabilitation planning, conduct, and monitoring of treatment, discharge planning, and patient and family education.

The health care team is a group of health care professionals from different disciplines who share common values and objectives (3). Halstead performed a literature review, covering the years 1950 to 1975, on team care in chronic illness and concluded that a coordinated team care approach appears to be more effective than fragmented care for patients with

long-term illness (3). More recently, the efficacy and efficiency of team care has continued to be lauded (1,4–9).

Writing physical medicine and rehabilitation (PM&R) therapy referrals, equipment prescriptions, and coordinating care requires the skills of a well-rounded clinician who is adept in both therapy and patient interactions to form an effective health care team individualized to the needs of that particular patient. Deficits in knowledge base or team and patient interaction skills lead to suboptimal treatment plans and care. The well-trained rehabilitation medicine specialist is able to develop comprehensive PM&R treatment plans of substantial detail when warranted. The degree of documentation and specification required depends on the mode of team interaction and treatment adopted by the professionals involved. Effective participation in treatment planning, nevertheless, requires the ability both to generate and to support the rationale behind multiple interventions as well as a thorough knowledge of the methods and systems required to achieve a particular rehabilitation goal, within each of the disciplines involved. These interventions must be appreciated in terms of their impact on function as well as on each patient's pathophysiologic processes.

Treatment plans are generated from goals that arise from the problem list developed during evaluation. The evaluation (see Chapters 1–3, 9 and 18) results in a set of identified problems that can be classified in various ways but typically are organized as medical, rehabilitation, and social problems. A set of goals or desired treatment outcomes is generated, along with an initial estimate of the duration of therapy necessary to accomplish each. Such goals assist the treating professionals in establishing therapeutic, discipline-specific goals that serve to support the overall medical rehabilitation plan, assist in identifying target skills that will be required to reach these goals, and serve as the foundation of a comprehensive treatment plan. This plan is a tool that patients, families, therapists, and other treating professionals examine for prognosis and expectations. It forms the basis from which all team members may suggest additions, deletions, methods of achievement, or modifications. The treatment plan is not a static document but rather remains dynamic as goals are accomplished, new goals are

**FIGURE 13-1.** Multiple caregivers that may be required in comprehensive rehabilitation.

identified and added, or some goals, which become irrelevant or unachievable, are eliminated.

Treatment strategies are developed to accomplish the identified goals. The specific strategies can be physician-directed, therapist-directed, or, ideally, mutually derived by the patient and team through the interdisciplinary process. The rehabilitation

medicine specialist should be knowledgeable about all pertinent therapies, their methods and modalities, and the potential benefits and risks of each, in order to optimally apply the specific interventions desired from each therapy specialty that will help to accomplish the desired patient goals. The availability, benefits, and risks of adaptive equipment and their use to facilitate

independence in activities of daily living (ADL), improve mobility, improve communication, maintain leisure activities, and decrease pain must be well understood to be prescribed and proscribed appropriately. A knowledge of expected effects and potential side effects, as well as a pathophysiologic and pharmacologic knowledge base, allows therapeutic interventions to be made with the least possible morbidity. This occurs when treatment is supervised by a physiatrist who can offer appropriate precautions and monitoring of referrals and prescriptions. The comprehensive treatment plan is initiated by referrals, prescriptions, and direct physician interventions. Factors that influence the form and details of the written therapy referral or equipment prescription include team communication needs, styles of interaction, and need for ongoing quality control.

Health care teams may be classified into one of four groups: the traditional medical model, the multidisciplinary

model, the interdisciplinary model, and the transdisciplinary model. These will be discussed in detail later, along with pertinent regulatory issues, within the context of the communication styles and needs of these differing team interactions.

## TEAM DYNAMICS

The focus of the comprehensive rehabilitation team is the well-being, quality of life, and functional reintegration of the patient into all aspects of life. An effective team is efficient in reaching its goals and creates an exciting and stimulating work environment for its members. Douglas McGregor developed one of the first descriptions of an effective team, noting that it must have the 11 characteristics outlined in Table 13-2 (6). When a team exhibits McGregor's characteristics, it has a

**TABLE 13.2** McGregor's Characteristics of an Effective Work Team

1. The atmosphere tends to be informal, comfortable, and relaxed. There are no obvious tensions. It is a working atmosphere in which people are involved and interested. There are no signs of boredom.
2. There is a lot of discussion in which virtually everyone participates, but it remains pertinent to the task of the group. If the discussion gets off the subject, someone will bring it back in short order.
3. The task or the objective of the group is well understood and accepted by the members. There will have been free discussion of the objective at some point, until it was formulated in such a way that the members of the group could commit themselves to it.
4. The members listen to each other! The discussion does not have the quality of jumping from one idea to another unrelated one. Every idea is given a hearing. People do not appear to be afraid of being foolish by putting forth a creative thought even if it seems fairly extreme.
5. There is some disagreement. The group is comfortable with this and shows no signs of having to avoid conflict or to keep everything on a plane of sweetness and light. Disagreements are not suppressed or overridden by premature group action. The reasons are carefully examined, and the group seeks to resolve them rather than to dominate the dissenter. On the other hand, there is no "tyranny of the minority." Members who disagree do not appear to be trying to dominate the group or to express hostility. Their disagreement is an expression of a genuine difference of opinion, and they expect a hearing so that a solution may be found. Sometimes there are basic disagreements that cannot be resolved. The group finds it possible to live with them, accepting them but not permitting them to block its efforts. Under some conditions, action will be deferred to permit further study of an issue between the members. On other occasions, when the disagreement cannot be resolved and action is necessary, it will be taken but with open caution and recognition that the action may be subject to later reconsideration.
6. Most decisions are reached by a consensus, in which it is clear that everybody is in general agreement and willing to go along. However, there is little tendency for members who oppose the action to keep their opposition private and thus let an apparent consensus mask real disagreement. Formal voting is at a minimum; the group does not accept a simple majority as a proper basis for action.
7. Criticism is frequent, frank, and relatively comfortable. There is little evidence of personal attack, either openly or in a hidden fashion. The criticism has a constructive flavor in that it is oriented toward removing an obstacle that faces the group and prevents it from getting the job done.
8. Team members are free in expressing their feelings as well as their ideas both on the problem and on the group's operation. There is little pussyfooting, there are few hidden agendas. Everybody appears to know quite well how everybody else feels about any matter under discussion.
9. When action is taken, clear assignments are made and accepted.
10. The chairman of the group does not dominate it, nor does the group defer unduly to him or her. In fact as one observes the activity, it is clear that the leadership shifts from time to time, depending on the circumstances. Different members, because of their knowledge or experience, are in a position at various times to act as resources for the group. The members use them in this fashion and they occupy leadership roles while they are thus being used. There is little evidence of a power struggle as the group operates. The issue is not who controls but how to get the job done.
11. The group is self-conscious about its own operations. Frequently, it will stop to examine how well it is doing or what may be interfering with its operation. The problem may be a matter of procedure, or it may be a member whose behavior is interfering with the accomplishment of the group's objectives. Whatever it is, it gets open discussion until a solution is found.

built-in feedback mechanism through which it constantly monitors itself and maintains its effectiveness. When a team is not functioning well, effective function can be developed or restored through the process of team building (6). Team building requires commitments of time and energy, but the rewards of improved patient outcomes and satisfaction of the team members are worth the effort (6,10,11).

A newly formed team, or a team with several new members, faces several major tasks if the team is to function effectively (6,11). The members must build a working relationship and establish a facilitative climate. This is particularly challenging in training atmospheres, since new members are frequently being added or removed for new rotations, and new trainees must learn and adapt to the culture of the permanent team in which negotiated roles have already been established. New teams must work out methods for setting goals, solving problems, making decisions, ensuring follow-through on task assignments, developing collaboration of effort, establishing lines of open communication, and ensuring an appropriate support system that will let team members feel accepted yet allow open discussion and disagreement. In a newly formed team, it is advisable to designate meetings in which members can share personal expectations and develop working policies.

## CONFLICT AND DISAGREEMENT

Conflict is a normal, necessary, and not necessarily destructive part of team development (7,10). The potential for conflict is high in health services organizations (12). How it is handled will determine its effect on team objectives and the group process. A good rehabilitation team creates an atmosphere in which members can agree to disagree without making personal accusations or faulting each other's personalities. In this atmosphere, conflict can be used as a vehicle for growth and innovation.

The interactionist perspective is one current view toward conflict. According to this view, a certain level of conflict is healthy and leads to a group that is viable, self-critical, and innovative. A group can have too little conflict. Without conflict, it may be viewed as harmonious, cooperative, and tranquil, but the team may become apathetic, noninnovative, and nonresponsive to needs for change and may show low productivity. Team members may leave the apathetic team because they are bored. If this occurs, then it becomes the responsibility of team leaders to stir up enough conflict or tension to promote creativity, innovation, and productivity among the team members. The manager who creates conflict must use great skill to see that the conflict does not accelerate to the point where it becomes disruptive, divisive, or chaotic. If conflict is not controlled, then communication suffers, cooperation ceases, and the quality of patient care decreases (7). When conflict repeatedly occurs with no resolution, action must be taken to restore the team's effectiveness. An appropriate setting for conflict resolution is a team-building session.

## TEAM BUILDING AND DEVELOPMENT

A group of professionals brought together for the purpose of helping a particular patient or set of patients will not automatically form the most efficient and effective force to accomplish that purpose. Understanding the factors that lead to the development of a team in which members are synergistic in their care of patients is of paramount importance to the physiatrist. To make interdisciplinary rehabilitation teams effective, Rothberg believes the following functions must be performed (13):

- Show/teach team members how to work together and provide sufficient practice time in teamwork.
- Ensure that all members learn, understand, and respect the knowledge and skills of others.
- Develop clear definitions of the roles and behaviors expected of team participants and lessen ambiguities regarding expectations of others.
- Encourage use of the full potential of each member.
- Direct attention to initiation and maintenance of communication and to the breaking down of barriers to interdisciplinary communications.
- Attend to the maintenance of the teams in the same way that other organizations engage in activities that strengthen their cohesion and offer satisfaction to their personnel.
- Acknowledge that leadership should shift as necessary in terms of the patients' needs.
- Ensure that the person in the leadership role respects the other members, as evidenced by consultation, active listening, and their inclusion in planning.
- Develop an internal system for demonstrating the accountability of each team member to the group, as well as to the institution in which the team practices.
- Develop a process to acknowledge conflict as it arises and to address it in a manner that strengthens the group and its members.

Table 13-3 lists individual characteristics that help one integrate into an interdisciplinary health care team. A professional who is unwilling to accept such roles cannot participate in a significant way in the interdisciplinary health care process.

**TABLE 13.3** Personal Characteristics of Successful Interdisciplinary Team Participants

1. Accept differences and perspectives of others
2. Function interdependently
3. Negotiate role with other team members
4. Form new values, attitudes, and perceptions
5. Tolerate constant review and challenge of ideas
6. Take risks
7. Possess personal identity and integrity
8. Accept team philosophy of care

## New Team Development

Initiating an effective team is a particular challenge. No matter what type of team is being developed, whether formal or informal, multidisciplinary, interdisciplinary, or transdisciplinary (as defined later), or a business group or committee, five basic stages of group development are encountered (Fig. 13-2). These are (a) forming, (b) storming, (c) norming, (d) performing, and (e) adjourning (14).

- During the forming stage, initial entry and identification with the group are the primary concerns. Group members are interested in what the group can offer them and what they can offer the group. During this stage, individuals are usually on their best behavior and may temporarily overlook conflicts for the good of the group.
- *Storming* is the most difficult stage and is characterized by high emotional tension. The level of trust becomes low during this phase. Team members tend to pressure the rest of the group to accept their preferences. Status and control in the group may become an issue during this phase. Cliques and coalitions may form here, and “hostility and infighting” (14) are

common. During this phase, members begin to understand one another’s interpersonal styles and learn to interact within those parameters (15). Team members also attempt to find ways to work toward the team’s goals while they seek concurrently to meet their individual needs.

- The *norming* phase is a transition to more comfortable and stable interaction and is referred to as *initial integration*. Balance begins to emerge during this phase, and the team begins to function more as a unit. This initial balance is not completely stable and can give way at any time, but balance and focus are usually reestablished fairly quickly. The newfound harmony usually comes as a great relief after the storming and may become the primary objective of the team for a period of time. Trust improves; however, the group has not yet matured, and the balance between group needs and individual needs is precarious.
- *Performing*, also referred to as complete integration, is characterized by maturity and a high level of functional efficiency. Complex tasks and disagreements no longer suspend or preoccupy the group. They are quickly resolved, often creatively, and the group moves on toward goal accomplishment. Trust is a key component of the successful team and becomes very high during this phase.
- The *adjourning* phase occurs when the team disbands. The ability to do this and reconvene in the future as needed is the true test of a team’s integration, maturity, and ultimate success.

The physiatrist, as a team leader, must appreciate that these phases of team development are normal, realizing that to some extent they are inevitable, are acceptable, and represent progress toward the desired goals of an effective and efficient team (14). Leading the team through these tumultuous times takes calm, steady leadership, and the leader must have the ability to remind the members of the group of these normal phases as they pass through them, with the goal of something better resulting eventually. The team must be reminded that complete integration is the goal, but this may not necessarily occur without first going through these other, less effective and efficient phases of negotiation. The leadership qualities defined by Lundberg should be cultivated by rehabilitation team leaders approaching this task (Table 13-4) (16). During the storming and early norming

**FIGURE 13-2.** Phases of new team development. (Modified from Schermerhorn JR, Flint JG, Osborn RN. *Organizational Behavior*. 7th ed. Philadelphia, PA: John Wiley & Sons; 2000:178–181.)

**TABLE 13.4** Some Qualities of a Leader

- Knows where he or she is going
- Knows how to get there
- Has courage and persistence
- Can be believed
- Can be trusted not to “sell out” a cause for personal advantage
- Makes the mission seem important, exciting, and possible to accomplish
- Makes each person’s role in the mission seem important
- Makes each member feel capable of performing his or her role

phases, extra care needs to be taken to avoid the appearance of selling out for personal gain during this time of naturally high distrust. Emphasizing the value and importance of each member will help to establish trust and facilitate progress through these tumultuous phases of team development.

### Established Team Complacency

Another factor that may be detrimental to the team's effectiveness is complacency among established teams (2,6,7). Whereas much transitional energy is present on initial team development and negotiation of roles, a mature team may lose its edge by accepting routine patterns of behaviors even when change is indicated. A complacent team may be recognized by one or more of the following characteristics: the same members seem to be doing the same things the same way year after year despite advances in the field; products prescribed are predictable; new members transfer out of the team because of the lack of challenge; there is a fear of, or resistance to, risk taking; and the rewards go to team members with average performance. These characteristics are especially detrimental to the rehabilitation team because external conditions that define the team's direction and individual patient's needs are always changing.

Despite similar diagnoses, each patient presents a unique picture; thus, treatment goals and procedures should always vary in some customized way. Treatment techniques should change in response to new research finding, and creativity and problem solving should be important to the operation of a rehabilitation team. Steiner has identified the following characteristics of a creative team: unusual types of people, open channels of communication, interaction with outside sources, openness to new ideas, freedom (i.e., not run as a "tight ship"), an atmosphere in which members have fun, rewards go to people with ideas, and risk taking occurs (2,6).

### Barriers to Communication

Communication networks associated with rehabilitation are complex, and there are many potential barriers to effective communication (2). Understanding flows of communication, natural barriers to effective communication, and strategies to overcome communication barriers can improve internal communication within the rehabilitation team and health care organization, and thus improve patient care. Communicating well in a rapidly changing health care market, especially external communication with stakeholders outside the rehabilitation facility, can benefit the health care organization in ways that ensure the health, or even survival, of the organization. For example, the rehabilitation organization that communicates well may benefit in terms of being selected as the first-choice provider of rehabilitation services, obtaining contracts at favorable reimbursement levels, or helping to establish favorable regulatory policies (17). Communication skills enhancement is also important for marketing to external stakeholders, as emphasized by CARF (Commission on Accreditation of Rehabilitation Facilities) (18).

An important issue in facilitating rehabilitation team communication is the identification and resolution of barriers

to communication. Given and Simmons have identified communication barriers that can interfere with the achievement of treatment goals (11):

- Autonomy
- Individual members' personal characteristics that may contribute to personality conflicts
- Role ambiguity
- Incongruent expectations
- Differing perceptions of authority
- Power and status differentials
- Varying educational preparation of the patient care team members
- Hidden agendas

These barriers stem from interpersonal, interprofessional, and practice issues, and these are not intrinsic defects of the team concept (11).

A special barrier to effective communication on rehabilitation teams is the presence of many professional disciplines in rehabilitation, particularly the differing perspectives of professionals with a physical background (e.g., physiatrists and physical therapists) and a psychosocial background (e.g., psychologists and social workers) (19). This adds strength to the holistic assessment and consideration of all aspects of the individual patient's life needs but can permit a frustrating set of varying backgrounds, priorities, and initial perspectives that may not be well understood by other team members of a differing discipline. A portion of this barrier can be varying definitions and understanding of rehabilitation-related terminology by different members of the rehabilitation team. A recent study provided objective evidence that members of rehabilitation teams have "a disturbing lack of common understanding for some basic rehabilitation terminology" and that "only about half of the personnel providing rehabilitation services are currently sensitive to this issue" (20). The authors suggested several courses of action for this problem: alert rehabilitation professionals that it exists, adopt a standardized rehabilitation glossary for the team, avoid the use of vague terms, define terms operationally, and express descriptions of patients and their progress objectively using standardized functional assessment instruments (20). The use of a communication instrument to help keep the information comprehensible, relevant, and compact can help improve discussion between professionals with different backgrounds (19).

Lack of effective communication can be detrimental to the rehabilitation process and uncomfortable for team members. Time must be designated to maintain an effective team process and to help overcome any existing communication barriers. When a team is functioning suboptimally because of conflict, complacency, or poor communication, the problem can be resolved through the team-building process (6). Dyer cites three prerequisites for conflict negotiation:

1. All parties must agree to come together and work on the problems.
2. Members must agree that there are problems that need to be solved and that solving them is everyone's responsibility.

3. Members accept the position that the end result is that the team will communicate better, thus enhancing the rehabilitation process (6).

Once these prerequisites have been met, the team identifies the conflicts or barriers in need of resolution. It is important that concrete suggestions be made for the resolution of these problems and that the team agrees on the solutions. This creates a problem-solving session rather than a detrimental process in which the members attempt to determine fault or place blame. Once solutions are agreed on, each member has the responsibility to follow through according to his or her role.

An outside consultant may be extremely helpful, since some signs of poor team function are more easily discerned by an outsider (6). Other symptoms are more easily observed by team members, but an outside consultant can help interpret and resolve these symptoms. The consultant can guide the team away from interpretations of problems that are not likely to lead to resolution, such as erroneously labeling incomplete or inadequate conflict resolution as personality conflict, or placing blame rather than finding effective solutions (6). Consultants can guide the team toward constructive ways to resolve problems such as appreciating the expectation theory, which simply states that negative reactions can be predicted whenever the behavior of one person violates the expectations of another (15). A vicious cycle of escalating conflict can result when the negative reaction itself violates the expectations of the first person. However, because this theory focuses on behavior rather than personality, it allows a greater possibility for conflict resolution. If the parties involved, or even one of the parties, can identify the behaviors that violate expectations, then behaviors can be changed or agreements can be reached. Team members can then reward one another's behaviors rather than negatively reinforce them (6,15). Appreciating our differences and anticipating how others desire to be treated, including how they prefer to communicate, has been called the Platinum Rule (15). A consultant can help the team learn to sustain healthy communication by developing its own internal mechanisms for problem identification and diagnosis, planning remediation, implementing changes, and evaluating its own results in a healthy feedback loop. The beneficiaries of healthy communication on the rehabilitation team are both the patients and the team members.

It is especially important that health care teams and organizations be able to manage a particular type of conflict—the conflict that arises when something goes wrong. Even in the best-managed organization, things will go wrong. In a health-care organization, the result of mistakes can be injury, pain, suffering, or even death. In such cases, the rehabilitation team and the organization also experience distress. There are always ripple effects that can affect multiple stakeholders inside and outside the organization. Excellent communication skills in this situation can contain the damage and may help to redress the consequences, the most difficult step. Healthy communication can help to build trust and even strengthen future relationships with affected stakeholders, and demonstrate a proactive approach toward helping to prevent recurrences of similar mishaps (2,17).

## REHABILITATION TEAM COMMUNICATION METHODOLOGY

Comprehensive medical rehabilitation requires the interactions of multiple caregivers to provide the breadth of services needed by people with physical and cognitive impairments (3,4,21,22). Patient needs range from acute and chronic medical problems to physical impairments, their complex interactions, and the impact each has on the patient's psychological, vocational, and social integration. The primary goal of interactions between care providers is communication of the patient's needs and coordination of his or her efforts in a synergistic manner (23). Physician-initiated prescriptions, referrals, or orders are written communications that are intended to provide for patient needs by initiating the services to be provided by multiple caregivers. The form such written communications take depends in part on the style of interaction adopted by involved professionals. Redundant, poorly coordinated, or incomplete care can occur when a patient's desires and needs are addressed from multiple vantage points without effective communication and coordination among the different caregiving professionals. Despite the widespread perception that a coordinated team effort enhances the effectiveness of such complex patient care, definitive studies are not available to prove this point. The results of the available studies have varied outcomes related to different measured variables (4,5,7).

Accrediting agencies such as CARE, and, more recently, The Joint Commission (TJC, formerly known as The Joint Commission on the Accreditation of Health care Organizations/JCAHO), and federal regulations in certain instances, require "interdisciplinary teams" (5,9,24,25), yet many styles of interaction exist that are influenced in part by the practice environment (26). Four general styles of interaction between physicians and other professional caregivers will be discussed: the traditional *medical model* without a formal team; the *multidisciplinary team*, which some call the traditional medical model of team interaction; the *interdisciplinary* model; and the *transdisciplinary* model. Each model's advantages and disadvantages are outlined, and its impact on prescriptions, orders, referrals, and treatment plan writing is discussed. These four models of interaction are described in pure form, though features of each are often combined to take the greatest advantage of the benefits each model's features may offer for a particular practice setting. Effective team dynamics and communication discussed earlier are always important, but they are especially necessary for successful implementation of the interdisciplinary and transdisciplinary models.

## STYLES OF INTERACTIONS

### Medical Model

Traditional medical care results in a model in which a physician attends to the patient's needs. If services of another discipline are desired, that professional is consulted and given either specific or general requests for assistance to meet the needs of the

patient as determined by the attending physician. The quality of the service rendered by the consultant, and thus future consultations, depends on meeting the needs of the patient and the attending physician. The consultant identifying additional needs would usually discuss them with the attending physician before proceeding with the additional treatment, in recognition of the fact that the attending physician may have additional information and insight not available to the consultant. This traditional system results in a clear chain of responsibility that continues to be well respected and is reinforced medicolegally. This traditional autocratic model of leadership, in which the physician assumes an authoritarian role and other team members obey, is not effective in the rehabilitation setting (10). Multiple consultations may result in many professionals doing multiple tasks. Coordination of these efforts by the attending physician or among the involved professionals can often be difficult or incomplete, resulting in less efficient and sometimes redundant patient care. This is one of the major disadvantages to the medical model of patient care (21,23,27).

Rehabilitation professionals have recently favored the concept of “client-centered therapy.” This is not meant to trivialize the patient’s needs, as physicians may suppose, but rather to emphasize the patient as the director and arbiter of the interventions according to the patient’s own desires (28). The term *client* is used in the place of *patient* in order to indicate that the role is an active one. The client, his or her caregivers, and the service providers enter into a collaborative relationship with the assumption that the client is the most knowledgeable about his own functional needs. The professionals advise and educate and assist in creating an optimal environment for the client to achieve independence in those areas that the client has identified as being important. Some advantages of this approach include empowerment and decreased dependency for the client, and a truly individualized treatment program, since each patient identifies the issues that he or she wishes to master. However, client-centered care is challenging to provide within the structure of current health care systems, which emphasize professional assessment and medical necessity over patient desires in establishing allowed treatment interventions. It also

assumes a fluid interaction that can be problematic within the bounds of the medical model in which a particular attending-defined problem was the cause for the initial referral and for which authorization for treatment was received.

Medical ethics in recent decades has prioritized patient autonomy over attending beneficence (paternalistic actions deemed by the practitioner to be in the patient’s best interest), which is also consistent with patient-centered care (2,29,30). The medical model, as compared with more team interactive models in which the patient is part of the team, is not particularly well suited for patient-directed care because of the additional effort required of the physician in this system. This is because all therapies and consultant plans are coordinated by the attending, and not by the patient. For patient autonomy to have priority, the full weight of patient education, including advice regarding all possible interventions and their respective risks and potential benefits, and recommendations is borne by the attending physician. This has become more difficult in an era of time-limiting managed care. Indeed, much of the decision making over what is best for the patient’s health care is defined by what the patient’s health insurance is willing to cover and is frequently removed from both patient and attending preferences by the coverage certification mechanisms of managed-care systems. These decisions are based more on economic considerations than on considerations of optimal health benefit.

### Multidisciplinary Team Model

The multidisciplinary team model provides a means for multiple professionals who require frequent interactions to meet and coordinate efforts on a consistent basis. The multidisciplinary model is analogous to the classic pyramid-shaped model of management, which features vertical communication between supervisor and subordinates. It typically remains an attending physician–controlled team in which most interactions are between consultants and the primary attending. Discussion between consulting professionals is held to a minimum or, when necessary, directed by the attending physician. This emphasis on vertical communication (Fig. 13-3) is

**FIGURE 13-3.** Multidisciplinary team conference structure. Vertical communication (solid lines) may serve to limit horizontal communication (dotted lines) between team care providers.

evolved from the medical model attending physician's role and relationship with consultants (26).

Team conferences can be conducted efficiently with such clear lines of authority and control, but lateral communication may suffer (27,31) (see Fig. 13-3). This tendency to impede the free, horizontal flow of communication between the team members is recognized as an obstacle to the optimal use of each participant's specific expertise and problem-solving skills. This may negate the possible group synergism that can create a product greater than the sum of its parts; or, in clinical terms, a care plan better than any one participant could have developed alone (26,32). The interdisciplinary team model does attempt to improve this communication and enhance group synergism, thus fostering a sense of mutual authority and responsibility (22,31,32).

### Interdisciplinary Team Model

Interdisciplinary teams benefit from lateral communication flow that occurs as easily as vertical communication in the multidisciplinary team. Because the interdisciplinary model is designed to facilitate such lateral communication, it is theoretically better suited for rehabilitation teams (34–36). The expected norm is group decision-making and group responsibility for developing optimal care planning (31). The problem orientation and ease of flow of lateral communication in the interdisciplinary team processes are similar in function to the project orientation and communication patterns of matrix organization (33,34). The patient is considered part of this planning group and has a central role in the team's considerations (see Fig. 13-1) (23,37,38). With the emphasis on mutual communication and responsibility, the patient care coordinating conferences may be led by any team member (Fig. 13-4) (27,39). One objective

**FIGURE 13-4.** In an interdisciplinary team, communication and decision-making mutualism are encouraged. One team member usually acts as the patient care coordinator, but lack of role dominance allows any team member to be eligible for this role.

of this model is to allow a freer exchange of ideas and thereby benefit from the group synergy concept (23,40). The interdisciplinary model has been described as a compromise between the benefits of specialization and the need for continuity and comprehensiveness of care (13). Its disadvantages can include considerably less time-effectiveness in completing patient care conferences. In theory, this inefficiency is offset by improved communication and better problem solving. Such teams also require considerable training in the team process, which generally is not received during the years of formal training in the individual disciplines (31). Team communication, development, and conflict resolution have been discussed earlier. This non-patient care training is expensive and does not ensure success (22,31,41). The commitments and personality traits found in the members of a successful interdisciplinary team are similar to those that engender good referral patterns between physicians (see Tables 13-3 and 13-5) (27,41). The physician may be uncomfortable with the team decision-making process because the physician is the one who must usually assume the greatest medicolegal responsibility for the team's actions and plans. There may be difficulty in having the physician complete the appropriate prescription for such team-generated plans, especially if the plans seem to be different from what the physician recalled or desired. Such conflicts are ideally resolved in team meetings, but delays in completion of the paperwork can jeopardize the optimal patient care.

### Transdisciplinary Team Model

Transdisciplinary teams, a more recent development, encourage not only communication but cross-treatment among disciplines. This atypical strategy has developed with the central focus on improving patient care through a team approach in which responsibilities are shared as in the interdisciplinary team and also where the normal boundaries of the various health care professions are blurred (42–45,47). These teams have mostly developed out of educational models (21,26,43,44) and have been justified on the basis of economic market forces, and in part by shortages in adequate numbers of therapy professionals (22,47,48). Cross-training, or multiskilling, of available teachers and aides is reported to be very helpful in providing the needed educational services. Such programs, when self-rated against no integration of the disciplines, are rated very favorably (43,45,47). The transdisciplinary team has also found favor with traumatic brain injury teams (26,47). Consistency of information exchange, with the patient intrinsic to co-treatment, is cited as an advantage (43,44,47). Furthermore, the exchange of information among disciplines is highly valued, with therapists or teachers noting expansion of their own professional expertise. A future corps of rehabilitation generalists as the main therapy providers has been predicted and advocated by some (47,48). Whether such informally shared professional knowledge and co-treatment lead to competent therapists in one another's fields is doubtful. The issues of technically competent care, professional society opposition, state licensure, and qualifications may limit the development of truly transdisciplinary rehabilitation on a widespread scale.

**TABLE 13.5** Personal Practices that Engender Referrals from Other Physicians

1. Never say anything bad about another physician, especially in front of a patient.
2. Send a typed note to the referring physician every time you see the patient as an outpatient.
3. Tell the referring physician in person or by phone of major changes in a patient's condition or treatment plan.
4. Never discharge another physician's patient from a hospital without informing that physician.
5. Do not provide care to referred patients, that is, in the area of expertise of the referring physicians, unless they have asked you to do so.
6. Regardless of your opinion on providing free care, do not refuse to see a patient who cannot pay or who has poor insurance if referred by a physician who also sends you many paying patients.
7. Do not communicate with the referring physician directly in hospital chart notes, particularly about an item of disagreement. Remember that the chart is a legal document. A lawyer may ask you to read your chart notes in court.
8. Get to know your referring physicians and their individual ways of handling patients. Avoid violating personal habits and biases.
9. Never send a patient who has been referred to you to another specialist unless the referring physician concurs.
10. Never leave a referring physician uninformed about the disposition of his or her patient. Physicians usually stop sending you patients if they know they will never see them again.
11. Answer consultations promptly.
12. Keep up your competence. Your referring physicians expect you to be on the cutting edge of your field.
13. Give the referring physician some suggestions or leads if you cannot definitively help him or her with a referred patient.
14. Let physicians' calls come through to you, but take a number and call back other persons.
15. Use a tickler file to keep up with patient needs.
16. Have a method for handling angry patients. Let them get all their emotion out—do not interrupt. Lower your voice and talk slowly. Never argue with their feelings, only with the facts of the case.

From Braddom RI. Practice issues in the hospital-based rehabilitation unit. In: Melvin JL, Odderson IR, eds. *Clinical Rehabilitation and Physiatric Practice*. Vol 7. 1996:31–41, with permission.

To further differentiate transdisciplinary from interdisciplinary or multidisciplinary team approaches, attributes from the literature have been defined by Walker and Avant (49). They define five premises that need to be met before the transdisciplinary approach is possible. They are role extension, role enrichment, role expansion, role release, and role support (42).

Role extension is a process whereby one's own discipline-specific knowledge is continually increasing (50). "Feeling secure in one's role and knowing that individual contributions are facilitating positive patient outcomes are essential components in creating an environment where each discipline is comfortable collaborating with the other" (51). Role extension involves understanding one's own discipline well and understanding how it compares to the aspects of other disciplines that can benefit the patient. Further, "having the security in one's own role leads to the resolution of role, turf, and status issues" (52).

Role enrichment is gaining awareness and knowledge of the other disciplines present on the team (50). Although health care personnel recognize and appreciate the various other professionals, the level of role enrichment to which this defining attribute refers is only achieved through a high degree of collaboration. Team members are encouraged to communicate, collectively plan and implement assessments, discuss results, and develop integrated treatment goals during team meetings (53).

Through team meetings, role expansion is expressed. Each team member from a particular discipline educates the others regarding his or her own expertise (52). Knowledge is shared as team members teach each other to make specific judgments and

decisions about interventions that transcend the boundaries of traditional roles (52).

The fourth critical characteristic, role release, is frequently lauded in the literature. Incorporating the skills acquired from other disciplines can help in problematic settings and enhance an individual's skill set, but such actions tend to blur the traditional discipline boundaries (54). A simple example would be that of a speech-language pathologist (SLP) helping a patient to sit more comfortably for speech therapy by applying proper body mechanics principles learned from a physical therapy colleague. This health care provider assumed responsibility for a needed task by applying techniques learned from another discipline.

Role support, the fifth defining attribute, would be best captured if the physical therapist should walk by at just the moment the SLP was helping the patient to a more comfortable position and gave the SLP feedback on how he or she was instructing the patient about body mechanics. Support of others and feedback about the implementation of a particular skill are the hallmarks of role support (50).

One application of the transdisciplinary team approach is the "arena" or group assessment, in which the patient and all therapists gather at one setting. One primary team facilitator conducts the initial assessment, with all the other disciplines observing, adding, or questioning as needed. This approach limits the number of times the patient is required to answer the same question or demonstrate the same activity or skill, and is considered the best for detecting difficulties because of its thoroughness by several specialties observing the same patient at the same time but from differing perspectives (55).

Though collegiality is enhanced by the transdisciplinary approach, the blurring of roles is discouraged by many specialties and regulatory agencies. The question is whether adequate competence can be developed by the informal training of transdisciplinary teams as compared with the years of formal training during which individual specialists have acquired their competence. Billing rules and regulations can also offer practical problems for appropriate billing for transdisciplinary treatment sessions as can regulatory requirements such as Medicare's 3-hour rule for Inpatient Rehabilitation Facilities (IRF), which credits only the actual time spent with the patient, not the time billed by each therapy professional.

### Which Team Approach to Use

Research is lacking on which of the previous models is most effective. The usefulness of such studies almost certainly will depend on which parameters are examined (i.e., team and patient satisfaction versus outcome). It may be that different models are more effective in different practice environments. The medical care, multidisciplinary team, interdisciplinary team, and transdisciplinary team models can be found in various settings in rehabilitation. The medical care model often is used in a freestanding office practice or in inpatient consultations in an acute-care hospital. This becomes especially true when referrals are made to therapists who are geographically distant or with whom frequent interaction may be difficult. Standing hospital programs that often include nonphysiatric physicians, such as cardiac rehabilitation, pulmonary rehabilitation, geriatrics, prosthetics clinic, myelomeningocele clinic, and the like, may use the multidisciplinary model with one physician in charge. Interdisciplinary teams generally consist of a stable population of health care providers who often can be found in association with specialized units in a comprehensive rehabilitation hospital, unit, or service. Transdisciplinary teams are more common when a stable population of professionals is to provide long-term care for a patient, and cognitive-educational needs are more prominent than intense physical needs.

These models of interaction are meant to enhance communication and thereby coordination of care. The practicing physiatrist may prefer one style over the others but often finds it necessary to communicate with patients and multiple care providers in all these models, or some combination, depending on practice setting. Specificity of orders and the methods in which treatment plans are developed will vary with the treatment and communication models that are adopted.

### Regulatory Organizations

The two primary regulatory organizations for rehabilitation programs, TJC and CARF, have standards (as noted above) addressing the rehabilitation treatment team and its composition as it relates to the individual needs of the person served. Both use the term *interdisciplinary team*, but they generalize the application of this term in ways that suggest that multidisciplinary teams as defined here would also qualify. CARF uses specific language about the interdisciplinary team and

its role and composition. Specifically, CARF indicates in the standard for comprehensive integrated inpatient rehabilitation programs, that the interdisciplinary team includes the following (18):

1. An occupational therapist
2. A physical therapist
3. A psychologist
4. A rehabilitation nurse
5. A rehabilitation physician
6. A social worker
7. A Speech Language Pathologist
8. A therapeutic recreational specialist.

The intent statement for this standard indicates that this dynamic, changing team always includes the person served, the rehabilitation physician, and the rehabilitation nurse. Other team members are determined by the assessment and individual planning processes (18).

TJC, although less specific, implies the importance of the interdisciplinary team approach. They indicate that, "An interdisciplinary team implements and coordinates planned treatment and services" (24). Its intent statement indicates that a "collaborative interdisciplinary approach" helps to achieve optimal outcomes. This plan is developed by the interdisciplinary team based on the needs of, and in conjunction with, the person served.

These regulatory standards do not address the various types of team formats specifically, but they do address the need for the person served to have a team approach and they define the various disciplines that are likely to be needed for the assessment, planning, and implementation of a comprehensive treatment plan for rehabilitation. This developed plan should be goal oriented and should produce positive, measurable outcomes for the person served (18,24). In addition, the regulatory requirements covering admissions to IRF should be considered. Currently, Medicare has specific requirements which must be satisfied prior to a patient's admission to an IRF. Per Medicare Benefit Policy Manual, 110.1—General (Rev. 1, 10-01-03), A3031001.11.A, HO-211.A, there are two basic requirements that must be met for inpatient hospital stays for rehabilitation care to be covered:

1. The services must be reasonable and necessary (in terms of efficacy, duration, frequency, and amount) for the treatment of the patient's condition.
2. It must be reasonable and necessary to furnish the care on an inpatient hospital basis, rather than in a less intensive facility such as an SNF, or on an outpatient basis.

In order to meet these criteria, the entire rehabilitation team, as supervised by the physiatrist, must document exactly how the patient has met the established admission criteria, including the above; why that patient must remain under the direct care of a physiatrist; how the patient's home and community life is practically and significantly benefiting from the established treatment; and why that patient cannot be safely and effectively treated in any, less intense, medical setting. Ideally,

**FIGURE 13-5.** The appropriate therapy specialties must be chosen for the patient's specific deficiencies. Examples from physical therapy, occupational therapy, and speech pathology are shown. Team coordination is required to prevent duplication of services and avoid gaps in services needed.

this documentation should begin when the patient is initially consulted for rehabilitation, must be clear upon the patient's referral to the IRF, and should continue throughout the IRF stay and also help to justify any outpatient therapy needs upon IRF discharge.

### Managing a Team Meeting

Although the rehabilitation health care team makes effective use of the combined expertise of all participants, this increased communication comes with a cost, which is time (2). Because much of the communication occurs during scheduled weekly staffings, or patient care conferences, these meetings must be run in an efficient and effective manner. A good team meeting is productive, stimulating, and goal oriented, and it involves creativity and problem solving through facilitated interdisciplinary interaction. The team leader, frequently the physiatrist, has the responsibility of facilitating the meeting, including maintaining the team's investment, productivity, and efficiency, while not inhibiting effective problem-solving contributions by all participants.

The structure of a team meeting can facilitate an effective team process. The simplest and most popular structure for team meetings is for a member from each discipline to give a progress report for each patient with opportunity for comment by other disciplines, especially when problems arise. This

structure can work well because each member tends to focus on the problems particular to his or her discipline. Where cross interactions occur (Fig. 13-5), the observations of other disciplines can be added during the discussion of progress in the common area or task.

Another approach is the problem-oriented agenda, where the problem list for each patient is reviewed in sequence. As each problem on the agenda is discussed, any team member may address his or her role in managing that particular problem. This format tends to promote team ownership to solve problems and to promote the synergistic interdisciplinary approach. It may be easier to keep the meeting goal-oriented because the problem list inherently defines the objectives for the meeting. However, this model requires more skill on the part of the team leader to keep the meetings efficient. For unusually complex problems, it may be prudent to delegate a subgroup to explore resources and possible solutions outside the larger group, and then have the subgroup report on their solutions, to be discussed by all, at the following large group meeting.

Regardless of the model used, it is the team leader's responsibility to keep the group focused and on task. This involves facilitating discussion, ensuring that ideas are understood, negotiating compromises, and clarifying responsibilities as well as minimizing non-problem-solving discussions (56). The documentation for the meeting should include an action summary of the agreed upon responsibilities with assignments and deadlines (Fig. 13-6).

Another important factor to facilitate communication within a team meeting is the physical setting. A specific meeting time must be designated, and team members must be committed to respecting this time. The meeting room's size, lighting, and temperature may help or hinder effective group process. Seating should allow face-to-face communication among all members. This criterion typically is met by sitting around a table or in a circle. Adequate physical space and time can help minimize some easily discernible barriers to effective communication (2).

### MULTIPLICITY OF CARE PROVIDERS

Comprehensive rehabilitation of people with physical and cognitive impairments can be an enormously complex task. The treatment goals are not disorder-specific but rather are patient individualized. The patient's psychological, religious, vocational, social, and personal needs, desires, and priorities are used to establish and prioritize rehabilitation goals. As an integrated member of the treatment team, the patient

Decision	Who is to do it	Date of completion	Date to report progress
Train to do safe independent car transfers with a sliding board	Jan Hoover, PT. Patient's mother is to bring her car in for use in the training sessions	May 23	May 27 (next scheduled team meeting)

**FIGURE 13-6.** Example of an action summary.

is expected to make a transition from the passive observer role, common during the acute treatment phase of an injury or debilitating disease, to an active participatory role. This shift in roles requires some patient orientation and education about the team process of evaluating and establishing goals. Patient autonomy should be supported and encouraged. Not only are the patient's medical needs addressed, but the psychological, social, religious, and vocational impacts of his or her disabling disorder require attention. Planning and facilitating all desired interventions can be accomplished best by each of the disciplines evaluating patient issues from their unique point of expertise. This knowledge from each professional must then be shared and formulated into a cohesive team plan of treatment.

Professional health care providers in the many disciplines common to rehabilitation (see Fig. 13-1, Table 13-1) spend many years acquiring specific skills necessary to effectively assess patient problems that fall within their professional expertise. This often includes the use of test instruments standardized for specific disorders. They learn to formulate and communicate their discipline-specific treatment plans and goals; educate patients, family, and other professionals; apply discipline-specific individualized interventions; and monitor patient progress. From their unique vantage points, they often uncover problems or issues not apparent to others. Although physiatrists have the broadest and most specific training among physician specialties in the issues involved in physical impairments, disabilities, and handicaps, their perspective generally will not be as specific in any one area as that of a therapist who focuses exclusively in that treatment area. Because the interventions required are more than any one provider can reasonably give, the expertise of many professionals is used to divide the needs according to areas of treatment or intervention expertise. To avoid fracturing or neglecting needs and goals that cross disciplines, team communication is used to formulate comprehensive treatment plans (22). The specific capabilities and general roles of the various health care providers commonly found on the rehabilitation team (see Fig. 13-1, Table 13-1) must be learned, well understood, and appreciated by the competent physiatrist for optimal application of these disciplines' capabilities toward enhancing the function of any particular patient.

Through the medical model, the patient often first encounters a physiatrist, a specialist in PM&R, by referral from another physician. With rehabilitation as the first goal, the physiatrist also will address associated medical problems unique to disabling disorders such as dysfunctional spasticity or optimal pharmacologic bladder management in the patient with spinal cord injury. The physiatrist often initiates the referrals to the necessary rehabilitation professionals. In the inpatient comprehensive rehabilitation setting, the physiatrist may be the sole physician involved.

A physiatrist is knowledgeable in the medical care issues of physically debilitating diseases and trauma, and has the broadest knowledge of the expertise available from each of the other team professionals (see Fig. 13-1). Identifying the

areas of patient need addressed by each of these professionals will ensure that appropriate resources are used (examples are shown in Fig. 13-5). The physician who specializes in medical rehabilitation must be aware of the techniques and therapeutic interventions available from each discipline that could have positive impacts on the care of patients and the interventions that are specifically contraindicated.

The appropriately consulted professionals, the patient, and the family form the rehabilitation team. The multitude of potential needs (e.g., medical, physical, psychological, vocational, educational, social, or spiritual) require multiple health care professionals to whom referrals, orders, or prescriptions may be sent. The combined input of the team members should form the basis for a coordinated, comprehensive treatment plan, including methods, goals, and estimates of length of time for completion of each. The treatment plan is dynamic and will require frequent modifications, updates, and revisions as the patient progresses.

## THERAPY REFERRALS AND ORDER WRITING

Therapy referrals and order writing are based on the initial evaluation (see Chapters 1 and 2). This may or may not include team evaluation input or consensus toward the treatment plan. In the medical model and multidisciplinary team model, orders and treatment plans usually are developed initially by the physiatrist, although they may be modified later as input is received from consultants. In the interdisciplinary team model, a period of evaluation by appropriate disciplines occurs before group development and consensus on the comprehensive treatment plan. Depending on the frequency of team meetings, this may introduce a delay before coordinated team interventions begin. In the transdisciplinary model, group evaluations are the rule, frequently allowing team treatment plans to be developed during the same evaluation and treatment session. Although time efficient, the transdisciplinary team may have less time available for deliberation or complex problem solving, since the concurrent patient treatment is occurring.

Once the problems and treatment goals have been delineated, the process of referrals and order writing can proceed. Often this can be facilitated by organizing problems into functional areas of concern. One organizational scheme is to list problems that are primarily medical in nature first, followed by functional limitations or rehabilitation problems, and then associated social–environmental problems. This allows orders to be broken down into medical, therapeutic, and psychosocial issues, although overlap of problems between these categories is common. Problem-based management of medical issues is now commonplace and integrates well into this scheme.

Interactions with the other professionals providing rehabilitation of complex problems require the physiatrist to possess both a diverse professional knowledge and a highly developed communication skills. The resources available should be applied optimally to obtain the best results for the patient. Through correct identification of the suitable providers, appropriate

referrals or orders communicate in as complete a fashion as possible without limiting creative problem solving or the reciprocal feedback that helps take full advantage of the available expertise. The format of these orders and referrals depends on the practice setting and the model of communication customary in that setting.

### Medical Model Referrals and Orders

In the outpatient setting, the practice may involve a well-integrated cohesive team, but more often the rehabilitation medicine specialist is a sole practitioner using community-wide resources. The former type is discussed later under the appropriate team model section. The latter outpatient practice is similar to inpatient psychiatric consultations in an acute-care hospital where individual therapy departments may exist without organized teams. In such settings, referrals and orders need to be more specific because frequent verbal feedback and clarification are not as readily available. Recording notes in the hospital chart helps with inpatient coordination and communication, but the chart is less available in the outpatient setting. Written prescriptions help avoid ambiguity and ensure that the patient is being treated as desired (see the section entitled “Written Protocols, Prescriptions, Orders, and Referrals”).

Although treatment recommendations ideally are based on clear physiologic rationale and clinically proven efficacy, such a literature base often is lacking or incomplete. Practitioners tend to be strongly influenced by their own successes and failures, applying lessons learned from past patients to future patients. If the psychiatrist does not know which approach to treatment a consulted discipline is taking, then it is unlikely any specific learning will occur from that interaction to benefit the rehabilitation physician's future management of similar patients. Thus, knowing the particular interventions to be used will help enhance the clinical acumen of the referring psychiatrist. Indeed, knowledge of how to prescribe therapeutic interventions in as much detail as is necessary is one measure the American Board of Physical Medicine and Rehabilitation examiners use to determine certification.

Another unique advantage the psychiatrist holds is the understanding of how therapeutic interventions affect the pathophysiologic process of disease states. This knowledge may serve as a safety check for his or her patients. The physical medicine aspect of psychiatry demands that the physics, biophysics, physiology, and pathophysiology of all prescribed physical modalities be well appreciated. This allows rational prescription of intensity, application methods, sites, duration, frequency, and precautions as warranted for such treatments. The psychiatrist must both prescribe appropriate interventions and proscribe inappropriate interventions. It is from such patient safety concerns that legal requirements for physician prescriptions were mandated. Without specific understanding of and concurrence in the treatment strategies used, this safety net of supervision is lost.

The major disadvantage in an extremely precise prescription format is that it may be taken as a signal by the consultant not to think, question, or be creative in addressing the

patient's problems but, rather, merely to perform the services as a technician. This perception may occur even though an order to evaluate the patient has been included, which often is legally required by state rules, whether prescribed or not. To minimize this potential negative impact on professional creativity and problem-solving expertise, requests for feedback should be specifically included. It often is helpful to request phone consultation with therapists, after their evaluation but before they begin treatment, to explore additional options or to convey significant yet sensitive information. If a phone consultation is requested, priority must be given to receiving such calls. Otherwise, this form of feedback and collaboration will not be reinforced enough to be maintained. Phone consultations may allow a better treatment approach to be pursued through modifications of orders by phone while providing the attending rehabilitation physician with the knowledge to adequately coordinate the specific interventions being applied. This will also help provide the order specifics often necessary for reimbursement of therapist-provided services.

Occasionally, team members are found who are unwilling to follow specific treatment orders and who proceed on a treatment plan based on their impression of what is in the patient's best interests, without consulting the prescribing physician. This violates the trust placed in the consultant and the rules by which one should engender referrals between health care providers (see Table 13-5) (57). Such practices also expose the therapist and patient to medically unsupervised care. If this situation cannot be corrected, the patient, for his or her safety and optimal care, should be redirected to more cooperative and collegial therapy professionals. General orders requesting “evaluate and treat,” sometimes because of lack of better knowledge, tend to promote such cross-purpose practices. Although this takes advantage of the therapist's creativity and expertise, it may restrict the physician's ability to supervise or coordinate patient care and may reduce the advantage of multiple professionals' synergism. Habitual poor physician support has, in part, encouraged some therapy groups to seek independent practices (also called direct access), available in 30 of the 50 states of United States, wherein no medical supervision is required (58). The relationship between a psychiatrist and consulted professionals should be collegial and mutually supportive because a domineering, rigid posture serves only to dampen creativity and problem solving among professionals and thus may diminish the quality of patient care (45). Managed care may restrict access to only certain providers. This adds weight to the value of being able to generate rapport, collegiality, and a sense of teamwork with many different rehabilitation professionals in many different settings.

A psychiatrist may evaluate patients in the outpatient setting, in which no other professional consultations are required. In this situation, instructions to the patient about medications, side effects, therapeutic exercise, home programs, or simple modalities (e.g., heating pads, ice packs, home traction) are the important communications. Informational brochures and pictographic flyers frequently are available from national advocacy groups (Table 13-6) or can be devised to help reinforce patient

comprehension and therefore compliance with the prescribed home program. Without the benefit of a therapist who interacts frequently with the patient and reports problems regularly, more frequent reevaluations may be necessary to ensure both compliance and progress. Increasingly, case management nurses are involved and may serve as valuable coordination resources and advocates for the patient with third-party payers.

When formal therapy is ordered, treatment referrals should specify any patient education or instruction desired. This includes requesting home programs and follow-up to verify compliance as necessary. Home health care services often terminate treatment because of funding constraints before all goals have been accomplished. Using therapy time before such terminations to provide patient and family training in home programs may significantly extend gains.

### Multidisciplinary Team Referrals and Orders

In the multidisciplinary team setting, the physiatrist may be a team member, a consultant, or more often one who acts as the primary attending physician. In such a group, the same specificity of orders often is required to initiate therapy but is modified more readily after input from team members at regularly scheduled patient care conferences. Priorities of goals and treatments also are more easily discussed verbally than in the written form. This allows some of the subtleties of comprehensive management to be more effectively conveyed and coordinated. Some degree of coordination between consultants also occurs at multidisciplinary conferences, but the flow of problem-solving creativity is not as free as seen with interdisciplinary team conferences. The format usually consists of consultants giving their reports (i.e., initial evaluations or progress since last conference) and recommendations. Other members ideally monitor the input, but the primary consultant determines the solution to any perceived problems and organizes all the input into a modified problem list and treatment plan. Many treatment modifications are made by verbal orders, with feedback guaranteed by regular meetings. In this setting, it is not necessary to include the time until next physician follow-up or desired frequency and mechanism of follow-up therapy reports based on the original orders.

### Interdisciplinary Team Referrals and Orders

The format of initial orders to consultants who comprise an interdisciplinary team often is based on requesting a general evaluation, with specific evaluation instruments and the comprehensive treatment plans to be discussed and mutually derived. Occasionally, to avoid delays in initiating therapy, broad categories of intervention also are requested (e.g., “ADL training”). The specifics, however, should be discussed and integrated by the team into a comprehensive individualized patient treatment plan. The shortcomings of a setting with no dynamic, creative problem-solving interactions may persist when the patient’s treatment plan is not specified and discussed but consists only of general orders for initial evaluations and general treatment, or treatment ordered according to a protocol (e.g., “tetraplegic protocol”). Such a generalized order format implies little attention to the patient’s specific and unique needs. It may be countered that therapists adapt the program to this patient’s unique needs, but each team member’s professionalism still functions in isolation, which defeats the advantage of the interdisciplinary team process. Although the mutualism of the interdisciplinary team implies no dominant specialty, it does not exclude any member from the responsibility to be interdependent with the creative input from other members in establishing his or her own specific treatment interventions. This means the physician should consider input from the physical therapist and therapeutic recreation specialist as well as from a consulting psychiatrist before starting antidepressant medications. Territory is both relinquished by all and embraced by all, although, in the end, specific needs and interventions are assigned by the group to those individual team members who have the greatest expertise in that area.

Because the comprehensive treatment plan is not developed solely by the admitting physician, and specific interventions are decided by mutual consensus among all team members, the actual specifics of treatment can be difficult to grasp in the training environment for the PM&R resident physician. This is especially true if the medicolegally required orders remain generalized or if the specific treatment plans are signed much later by the attending physician without the resident necessarily being in the loop. This may occur because only the attending signature is required to meet hospital and third-party payer rules. Much of resident training is funded by inpatient rehabilitation hospitals or units in which the interdisciplinary team process is most often used. It is necessary that not only the generalized order formats be appreciated but also the specifics of therapy interventions and efficacy be prescribed for other, less-integrated settings. If the specifics are not discussed in team meetings, then the full benefit of the interdisciplinary team process is not being realized. Many times, multidisciplinary teams with good mutual interactive skills will be labeled interdisciplinary, but each professional maintains full control of his or her specialty area, with little cross-disciplinary discussion of methods and approaches. Such teams remain multidisciplinary despite labels to the contrary. In this setting, general orders may become accepted but may be counterproductive to the educational process of the physician, the medical supervision

of the patient, and the collective group synergism that can enhance creative problem solving. Becoming interdisciplinary is threatening, challenging, and time-consuming, but satisfying, in increasing collegial relationships and in deriving optimal treatment plans. Marginally competent professionals become exposed, but the team process can partially compensate for such member weaknesses (5). Professional expertise is challenged by the team, and many are not comfortable in such a vulnerable position (see Table 13-3).

### Transdisciplinary Team Referrals and Orders

All members are involved collaboratively in treatments in the transdisciplinary team approach. Collective hands-on treatment is an excellent method for learning, especially when the information shared among the treating professionals is pertinent and applicable to the moment of care needs. Having another professional depend on your input as you are co-treating is both rewarding and self-affirming. The importance of each member's beliefs can be emphasized and appreciated in a very practical hands-on experience. The team member does not have to wonder whether a communication about a belief's importance was received adequately when it becomes essential to the treatment approach integrated between professionals during a co-treatment. Many reports on the transdisciplinary approach emphasize the high ratings such approaches receive by the treating disciplines (43,44,47). Collaboration and coordination of effort certainly are optimized because the disciplines have the opportunity to communicate throughout both the evaluation and the treatment of patients. There may not be a need for a formal team meeting apart from ongoing patient care, except as necessary to provide regulatory or third-party payer required documentation. If all the disciplines in comprehensive rehabilitation could be integrated sufficiently that each felt comfortable treating any patient's problem, regardless of usual discipline specificity, then a rehabilitation therapy generalist could be envisioned (47). Such a corps of professionals would certainly appreciate problems from a broader perspective and, in an era of shortage, allow for a certain ease of cross-coverage. The greatest impediment to such a development is the necessity by certification laws and ethical considerations of providing skilled, competent professional care (5,22). Billing also can be an ethical dilemma. Should a single patient treated for 1 hour by three co-treating professionals be billed for 1 hour of therapy or three? Should the therapy time be billed on the schedule of the best-paying specialty present or equally divided among the therapy disciplines treating? It remains an open question as to whether co-treatment results in each participating professional becoming more globally competent or merely exposes the patient to less than fully professional care in those areas in which the co-treating caregiver lacks certified expertise and competence.

The advantage of dynamic, fluid, and constantly changing treatment plans that adapt to the patient's changing status can be a disadvantage when such plans must be developed on the spot. This allows little time for deliberation or consideration of alternatives because treatment must be given promptly. Written

plans may not keep up with the current flow of treatment, causing difficulties when a patient must make the transition to other care providers. Indeed, written treatment plans often are generated as a retrospective report of the patient's past treatments and progress.

If the physician team member is a part of the treatment team, then any concerns about medical safety and medical treatment coordination can be addressed as treatment progresses. This, however, is unusual, with the rehabilitation physician often referring patients to such teams in which the physician will not act as a co-therapist. In such a setting, the more generalized order format may not allow adequate communication of the physician's concerns and treatment goals, especially because formal team conferences may not be frequent. Because the treating professionals may be addressing areas outside their specific expertise, the comprehensiveness with which all specific therapy issues are addressed may be of concern. In such a setting, it may be to the patient's advantage for the physician to write more specific and detailed orders to ensure that the breadth of patient issues identified by the physician will be addressed. Some mechanism to allow flexibility in approaches while maintaining direction toward the desired goals is important. Thus, treatment orders or referrals are written in a very goal-directed way, giving guidelines for treatment methods or intervention models. A mechanism for feedback on the approaches taken also is important to enhance the prescribing physician's supervision and learning experience. Without such interaction, prolonged ineffectiveness or perhaps even contraindicated approaches may result without the benefit of a physiatrist's professional expertise. Because of the possible professional "dilution" in the transdisciplinary approach, even closer re-evaluation of care by the prescribing professional may be indicated.

## WRITTEN PROTOCOLS, PRESCRIPTIONS, ORDERS, AND REFERRALS

### Communication

The purpose of physician-generated protocols, prescriptions, orders, and referrals is to communicate patient's needs adequately and to request services from another professional. In the case of medications, this applies to the prescription sent to the pharmacist. In rehabilitation, it applies to the services requested from the various professionals described earlier. The rehabilitation medicine specialist must use his or her expertise first to decide what the patient's needs are. The physiatrist's broad knowledge of the capabilities of various rehabilitation professionals allows selection of the appropriate consulting professionals (see Figs. 13-1 and 13-5). Each professional is then sent a referral or order, depending on the setting. The content depends on the team process in effect in that setting. Referrals in the medical model or multidisciplinary team model should include all elements listed in the first part of Table 13-7 to provide adequate communication (22). The referral should include a mechanism for feedback and possibly an invitation

**TABLE 13.7** Seven Requirements for Therapy Referrals

## Required of All Referrals

1. Discipline of therapist to whom referral is directed: may include referral to a specific team
2. Diagnosis for which treatment is being requested
3. Request for evaluation
4. Goals of treatment with expected duration
5. Intensity, frequency, and initial duration of treatment desired: may be modified after consultation with therapy professional according to patient's rate of progress
6. Precautions: include other diagnoses or problems that could impede or contraindicate certain interventions, and necessary patient monitoring during therapy with recommended limitations to maintain patient's safety
7. Mechanism for feedback, date, and signature: date when physician is to reevaluate the patient, request for phone consultation or progress reports, or implied team staffing if referred to an established team

## Specifics Possibly Needed in Therapy Referrals

1. (a) if a specific therapist is desired, it may be listed as "*Discipline/Attention: Therapist's Name*"
- (b) If to a specific team, may include each therapy discipline desired or left to be defined, implying referrals will be generated to all disciplines for an initial evaluation; specific therapy orders would then be determined at team conference
2. (a) Onset of diagnosis or associated problem
- (b) Include both physical problem and relevant medical diagnosis and onset
- (c) May include multiple relevant problems and respective underlying diagnoses
- (d) Associated psychosocial problems that may affect goals or outcome
3. (a) Specify desired testing and reporting mechanisms
- (b) Specify intervals between any retesting or reevaluation desired.
4. (a) Detailed short- or long-term goals usually based on problems listed above, or
- (b) Detailed component tasks to be accomplished and sequence desired
- (c) Estimated length of time expected to accomplish each of the above goals
5. (a) Location of therapy desired (e.g., bedside, department or gym, inpatient, outpatient)
- (b) Desired duration of each treatment session
- (c) Specific therapeutic modalities desired, with intensity, duration, frequency, and timing with other therapeutic interventions described (see Chapters 11, 13, 17–20)

- (d) Endpoints or decision points and criteria for increasing or decreasing therapy in general, or a specific intervention's frequency
- (e) Specific education for patient and mechanism to evaluate effectiveness of this teaching
- (f) Home program training desired, including timing or criteria for such transition
- (g) Nature of home program to be taught: frequency, duration, and intensity of modalities, therapeutic exercise, or other interventions
- (h) Handout materials specifically desired
- (i) Anticipated or desired home equipment training or trials
- (j) Duration until therapist follow-up, if any desired, to reverify or enhance compliances with home program and maintenance of gains
6. (a) Specifics of monitoring: desired type, frequency, timing during therapeutic interventions, and criteria to discontinue or specifically modify intervention
- (b) Criteria for immediate physician notification
- (c) Specific precautions to ensure therapist safety (e.g., infectious, patient behavior, or violence risks)
- (d) Specific modality precautions, given the patient's diagnoses
- (e) Complete list of patient problems or complete diagnosis list
- (f) May include physician's evaluation report
7. (a) Next physician follow-up date
- (b) Anticipated physician follow-up frequency
- (c) Possibly desired phone consultation before initiating therapy
- (d) Desired frequency of follow-up reports and mechanism (written or phone)
- (e) Details desired in follow-up reports
- (f) Third-party reporting required or desired
- (g) Criteria to discontinue or duration to continue therapy should physician follow-up not be obtained
- (h) Date or week desired first to discuss this patient at team conference
- (i) Frequency of team conferencing desired, especially if different from team's norm
- (j) Desired emergency health system to be activated should patient decompensate
- (k) Provision of phone, address, and paging numbers to contact the referring physician; mechanism for emergency contact provided

for pretreatment discussion as to the most efficacious plan of treatment. If such an approach is taken, priority must be given to responding to therapist-initiated phone consultations, similar to the courtesy that should be offered to referring physicians (see Table 13-5) (57). Referrals to interdisciplinary team members often are requests for evaluation, with the specifics of treatment to be discussed and agreed on at the next team conference, at which time a written treatment plan and orders will be developed. Referrals that are to be addressed by a transdisciplinary team can be performed in a way similar to the interdisciplinary team, if a post-evaluation conference can be planned;

otherwise, they are best left in the detailed format of the medical model. Protocols may be established by the collective consensus of a treatment team, especially for commonly seen disorders that require little variation in approach. These should be agreed on by all treating professionals before their implementation and often require significant development time. A protocol must not become an excuse not to think or customize the treatment approach according to the patient's unique needs and circumstances. All formats for orders should provide a mechanism for feedback, and the treating team should discuss any changes in treatment required as the patient progresses.

## Medical Necessity

A broad understanding of reasonable and medically necessary standards defined by the Centers for Medicare and Medicaid Services (CMS) is useful in identifying rehabilitation therapy needs of a patient. A prescription generated based on a good understanding of these guidelines allows for better medical justification of rehabilitation therapy needs. These standards are set around the definition of “skilled therapy” services as defined by CMS. These are used by rehabilitation therapy professionals to assist in determination of plan of care. CMS guidelines are used by many payer sources besides Medicare and Medicaid. The judgment of the physician and the needs of the patient, however, should always supersede a standard that may not be appropriate in a specific setting. Critical points in these guidelines include:

1. Skilled therapy: CMS states (59), “The services shall be of such a level of complexity and sophistication or the condition of the patient shall be such that the services required can be safely and effectively performed only by a therapist, or in the case of physical therapy and occupational therapy, by or under the supervision of a therapist. Services that do not require the performance or supervision of a therapist are not skilled and are not considered reasonable or necessary therapy services, even if they are performed or supervised by a qualified professional.” Only services that are skilled in nature are value added to provide benefit to a patient, per this definition. Chronic diagnoses, repetitive services, community/recreational services even performed by a therapist can be viewed as a non-skilled service.
2. Reasonable and necessary: CMS states (60), “While a beneficiary’s particular medical condition is a valid factor in deciding if skilled therapy services are needed, a beneficiary’s diagnosis or prognosis should never be the sole factor in deciding that a service is or is not skilled. The key issue is whether the skills of a therapist are needed to treat the illness or injury, or whether the services can be carried out by non-skilled personnel. There must be an expectation that the patient’s condition will improve significantly in a reasonable (and generally predictable) period of time, or the services must be necessary for the establishment of a safe and effective maintenance program required in connection with a specific disease state.”
3. Maintenance program: CMS validates the necessity of skilled services for setting up a maintenance program for chronic diagnoses and states (61), “The specialized skill, knowledge and judgment of a therapist would be required, and services are covered, to design or establish the plan, assure patient safety, train the patient, family members and/or unskilled personnel and make infrequent but periodic reevaluations of the plan. The services of a qualified professional *are not necessary* to carry out a maintenance program, and are not covered under ordinary circumstances. The patient may perform such a program independently or with the assistance of unskilled personnel or family members.” Although this allows more frequent interventions for chronic diagnoses, the intervention should be of very short

duration with a home exercise program as an ultimate goal.

Reviewing the following prescriptions will allow a better understanding of these guidelines:

### EXAMPLE 1

PROBLEM: 74-year-old male s/p CABG, now with generalized weakness and unable to return to golf.

GOALS: Return to golf.

INTERVENTIONS: Physical therapy referral:

Dated: \_\_\_\_\_

Dx: Deconditioning S/P CABG 6 weeks ago

Date of Onset: \_\_\_\_\_

Frequency: 2 to 3 times a week × 4 weeks

Goals: Improve strength to be able to return to golf activity

Precautions: Cardiac precautions: HR < \_\_\_\_\_; Systolic BP < \_\_\_\_\_; other: \_\_\_\_\_

Instructions: Please evaluate and assist with strengthening and endurance. Reduced strength in lower extremities, perform training in standing and walking endurance. Patient to return for follow-up in PMR clinic in 4 weeks.

CRITICAL REVIEW: Per CMS guideline, community/recreational/leisure goals are optimal goals and not functional goals. These are not medically justified goals for therapy intervention.

- Golf activity is a recreational goal: Cannot justify “skilled” physical therapy services
- Endurance goal: Skilled services cannot be justified. Research validates that endurance can improve with time and skilled services are not indicated.
- Skilled therapy can be justified if specific balance and gait deficits that affect daily function are identified in the referral.
- Patient might be suited for cardiac rehabilitation programs that are now generally run by nursing or are private pay programs.

### EXAMPLE 2

PROBLEM: A 67-year-old female with acute exacerbation of Parkinson’s. Unable to perform home exercise program (HEP) independently

GOAL: Independent with HEP

INTERVENTIONS: Occupational therapy (OT) and physical therapy (PT) referrals

Dated: \_\_\_\_\_

Dx: Acute Exacerbation of Parkinson’s

Date of Onset: \_\_\_\_\_

Frequency: 3 to 4 visits each for OT and PT

Goals: Independent with home exercise program

Precautions: Fall risk

Instructions: Patient with acute exacerbation of Parkinson’s disease. Now with increased difficulty performing existing HEP. Please evaluate for adaptive equipment at home for dressing and address challenges with independent HEP. Please add

new HEP as appropriate. Please address transfer training with adaptive equipment. Please send report to FAX: \_\_\_\_\_

CRITICAL REVIEW: CMS guidelines approve setting up of maintenance programs for chronic diagnoses.

- Goals are functional, are related to safety and address household function
- Exacerbation refers to acute change in a chronic condition
- Setting up home exercise program covered per “skilled” needs identified by CMS guidelines
- Goals and frequency relate to short duration of intervention

### Therapy Quality Control

Without appropriate follow-up, the efficacy of any intervention cannot be evaluated or documented. Referrals for therapy, and

any prescribed equipment or medication, require follow-up. Often what was desired and presumed to be well communicated by written prescription or referral by the physician is not what occurred with the patient and the therapist. Feedback enhances the accuracy of conveying the correct messages and should be encouraged (32). Receiving feedback helps the rehabilitation physician obtain a broader and more complete perspective on the patient’s required needs and provides information necessary to evaluate progress. A certain degree of feedback is built into the multidisciplinary and interdisciplinary models as well as the transdisciplinary model if the physician is a co-therapist. Otherwise, mechanisms to ensure feedback are essential to good written referrals and orders. Quality control requires not only feedback and follow-up but appropriate corrective actions (Fig. 13-7).

FIGURE 13-7. Treatment-planning algorithm.

In the medical model, the attending physician alone bears the responsibility for ensuring feedback, providing appropriate follow-up, and initiating additional contacts as problems arise. The physician's judgment determines whether outcomes are adequate and whether treatment is brought to closure. Table 13-8 shows examples of referrals and orders that arise from this model.

In the multidisciplinary team, the members give input as to whether goals are being achieved and, if not, why. Problems with progress can also be discussed in team conferences, with solutions derived between the consultants and the primary team-leading physician. Identification of problems and necessary corrective actions becomes a more joint effort as the consultants collectively discuss a single patient's care.

In the interdisciplinary team, a sense of mutual responsibility demands rapid identification and problem solving by the team for any problem perceived by a member. Solutions are achieved by interactive discussions, brainstorming, and finally mutual consensus over the optimum course to be taken. Problem identification and corrective actions are a team process. It is this process that forms the strength of the interdisciplinary team and occupies the greatest time in patient care team conferences.

In the transdisciplinary team, problems are agreed on so rapidly during treatment that larger-scale or longer-term problems may be ignored or not formally considered. If such a problem currently is affecting treatment, it should be solved by mutual discussion and problem solving. Feedback, discussion, and problem solving occur so fluidly and rapidly that the physician member may be left out until after a solution has been decided and enacted. This diminishes the value of the physician's expertise to the team and can create conflicts should the physician subsequently believe alternative approaches are indicated. Even if by mutual consent the treating therapist and patient concur, the patient may come to doubt the treatment team's or physician's expertise. More likely, the physician's opinion will be viewed as obtrusive, given the relative paucity of time he or she has been involved in the patient's team care. Thus, corrective action can be a disjointed process in the transdisciplinary model unless the physician is an integral co-therapist.

Diagnosis-related groups (DRGs), implemented in 1983 to cap Medicare expense growth, created incentives for improved efficiency in terms of hospital costs. This prompted the development of care paths in an attempt to optimize

**TABLE 13.8** Examples of Detailed Prescription for Durable Medical Equipment (DME) and Therapy Generated from a Problem List, Leading to Goals, which Lead to Specific Interventions

Problems	Peroneal palsy, likely recovery within 6 mo	Left shoulder adhesive capsulitis.
↓		
Goals	Eliminate toe catching with ambulation.	Improve shoulder external rotation and then abduction, while avoiding impingement, to functional and, if possible, normal range.
↓		
Interventions	<p>DME prescription: Please fit with off-the-shelf polypropylene ankle-foot orthosis set at 90 degrees, and provide single cane adjusted to patient.</p> <p>Diagnosis: Foot drop secondary to peroneal palsy; needed for more than 6 mo; medically necessary to provide safe gait. Date: _____</p> <p>Therapy referral: Date: _____</p> <p>P.T. X 1 visit</p> <p>Dx: Peroneal palsy with footdrop.</p> <p>Goals: Improved gait safety/efficiency and eliminate toe catching during gait; prevent heel cord contracture.</p> <p>Precautions: Mildly decreased sensation on foot dorsum, gait instability, chronic intermittent hepatitis B fluid precautions and train in the use of AFO.</p> <p>Please evaluate and train in the use of AFO; including donning, doffing, and skin checks. Teach home program for gastroc. stretching. Also train in proper gait, including stairs and rough terrain, with cane to be used until patient becomes comfortable with balance. I will follow up pt. in 2 wk; please send report. Thank you.</p>	<p>DME prescription: Please issue yellow, red, and green theraband exercise elastic cords.</p> <p>Diagnosis: Deficient rotator cuff on left; medically needed over 6 mo for proper shoulder function.</p> <p>Date: _____</p> <p>Therapy referral: Date: _____</p> <p>P.T. TIW (3 times per week) for 4 wk.</p> <p>Dx: Left shoulder adhesive capsulitis.</p> <p>Goals: Improve external rotation by 20 degrees and shoulder abduction by 30 degrees in 4 wk.</p> <p>Precautions: Patient S/P rotator cuff repair 12 wk ago with weak rotator cuff muscles and increased impingement risk; pulleys are contraindicated.</p> <p>Please evaluate and manually stretch left shoulder, including scapular mobilization, avoiding shoulder impingement, while applying ultrasound to anterior, then posterior joint to start at 1.5 W/cm<sup>2</sup> and adjust to highest level comfortable for 10 min at each site. Teach home program for self-stretching of external rotation only (abduction will be added later), and rotator cuff muscle strengthening with progressive therabands. Pt. will be reevaluated in 4 wk. Please send progress report, including shoulder active and passive range of motion measurements every 2 wk. Please call 123-4567 for any questions. Thank you.</p>

This level of specificity may not be required when working with a known therapist with whom treatment protocols have been previously discussed; however, the seven elements required from Table 13-7 should be included. This is for both patient safety, billing needs, and to optimize care.

hospital resource utilization. The CMS implemented a prospective payment system (PPS) in the year 2000 for rehabilitation hospitals, also called Inpatient Rehabilitation Facilities (IRF), which is in part based on the functional independence measure (FIM) plus diagnostic criteria defining categories of patients, called Case Mix Groups (CMGs), which serve to define reimbursement, similar to the DRG system for acute care (48,62,63). Besides increasing the efficiency of cost containment, managed care desires to document maintenance of quality. The ability to measure quality requires some degree of uniformity of approach across institutions for comparisons. Care paths, or protocols for patient treatment, help establish a greater degree of uniformity of patient care. Care paths are ideally targeted for populations for whom 75% are expected to follow a typical course. More customization is typically required in rehabilitation than for other medical care. Care paths are most easily developed for postsurgical patients in whom few complications are expected, such as elective orthopedic cases. In the acute-care setting, 20% to 60% shorter lengths of stay have been obtained by implementing such protocols. Few studies have been done in rehabilitation settings, but one study showed no impact on cost or length of stay when a care path was used versus the usual interdisciplinary team approach. The high level of coordinated care that already exists in comprehensive rehabilitation settings may explain this result (64).

Managed care dominates many markets, as had been predicted (65). Competition for these contracts and the quality improvement management techniques fostered by the TJC and CARF promote the development and implementation of care paths even in rehabilitation, where their value has yet to be firmly established (9,24,64). Care paths or treatment protocols have many labels, including critical paths, practice guidelines or parameters, clinical guidelines, clinical pathways, care maps, flow charts, anticipated recovery plans, or case management (64,66). Care paths for inpatient comprehensive rehabilitation units will become more common as managed care increases. The development of such paths always needs to be customized to each particular setting, ideally by an interdisciplinary team. It is hoped that such protocols will improve efficiency without sacrificing the individualization of care required by most complex rehabilitation inpatients.

The complexity and nonhomogeneity of comprehensive rehabilitation patients makes their study difficult (67,68). Despite poorer outcomes in terms of morbidity and return to community for skilled nursing facility patients compared to IRF patients as a whole, for the populations they serve, few randomized controlled trials of matched patients exist (68). CMS has tried to use evidence-based medicine as its standard, with the absence of evidence often being inappropriately attributed by many of CMS's fiscal intermediaries as evidence of lack of efficacy (69–71). CMS's pending fiscal shortfalls are well known, are severe and unresolved, and will continue to pressure denial of care that is not of specifically proven benefit over other perceived less expensive options including no care (67,68,71). This has and will continue to constitute a

dynamically changing scene from what is now considered the community standard of care to what the fiscal intermediary chooses to restrict from reimbursement.

## EQUIPMENT PRESCRIPTIONS

Prescriptions can involve not only needed therapies but also necessary adaptive equipment. The use of adaptive equipment or tools is an important component of the rehabilitation of people with disabilities (72,73). Frequently, appropriate equipment may represent the difference between being functionally independent and requiring the assistance of a caregiver to perform necessary tasks for self-care and ADL. The ultimate goal in rehabilitation is for the patient to achieve the highest level of independence possible. This requires the effective integration of adaptive equipment into the patient's individualized treatment plan as necessary (74).

The importance of adaptive equipment and devices is illustrated by the diversity of items available to enhance mobility or perform ADL (75). Adaptive devices and equipment are categorized according to the functional skills they are devised to facilitate. These include ADL (e.g., dressing sticks, sock-aides, rocker knife, reachers, etc.), mobility (e.g., gait aids, positioning and transfer equipment, wheelchairs, etc.), communication (e.g., picture boards, Passy-Muir valves, Electrolarynx, computer augmentation, etc.), environmental management (e.g., adaptations, environmental controls, etc.), and leisure and recreation (e.g., adaptive sports and leisure equipment, specialized prostheses, etc.). Concomitant with the availability of an increasing array of adaptive aids is the inconsistent evaluation of the efficacy of these devices (76). Information regarding development and research and printed information resources are variable in quality and content.

Changes in a patient's functional status through the rehabilitative process introduce another aspect of consideration in adaptive equipment use and length of need. Improved function through time could mean decreased need for adaptive equipment. However, patients with progressive neurologic conditions may require more sophisticated assistive technology if they are to be as functional as they wish to be. The goal would be the attainment of the highest level of independence with the least adaptive equipment. All these factors are part of the process for the selection of adaptive equipment.

Devices and equipment can be very costly. Costs can be minimized by using rentals or 30-day trial usage when utility is uncertain. When items are more unique and customized, costs increase, whereas more commonly used devices can be mass-produced and become more economical. Some costs may be decreasing because some adaptive devices are being increasingly used by a normative aging population to facilitate their self-care and functional performance (e.g., a reacher which is used rather than standing on a step stool to reach items in the closet or pantry, or a long-handled shoe horn that makes it unnecessary to bend over when putting on shoes, etc.).

Frequently, commercial devices must be adapted to the patient to provide for appropriate, individualized fit. Training also is required for the patient to achieve proper and optimum use of the equipment. In addition, the items of adaptive equipment on the market do not remain static, there are ongoing additions to the available repertoire. These changes can represent refinements on current items, new adaptations, or equipment using new technology.

**Types of Adaptive Equipment and Devices**  
**Self-Care and ADL Equipment**

Equipment that aids in self-care and facilitates the ADL constitutes a category that encompasses a wide variety of items. These adaptive devices generally contribute to the patient's independence in performing these activities, with the ADL dysfunction dictating the type of adaptive equipment needed. For example, a stroke patient may be able to perform only one-handed activities, owing to upper-extremity hemiparesis. Therefore, to facilitate eating, a plate guard and adaptive eating utensils such as a rocker knife may be appropriate. The use of the equipment should serve the two purposes of providing the patient with independence in eating a meal and releasing the caretaker from the supervisory or assistive task during the eating process. Other examples for this patient might include a suction-based hand brush to assist in hygiene and a dressing stick to help in performing dressing activities independently with one hand. (See Chapter 9 for additional details.)

The diagnosis, prognosis, and residual function of the patient indicate the types and extent of equipment (77,78). A general rule of thumb is that the more restricted the patient is in performing ADL, the more adaptive the equipment must be and the more extensive will be the collaboration among occupational therapists, physical therapists, and SLPs to provide adequately for the patient. Rehabilitation engineers also can be helpful team members, particularly when the custom adaptations are extensive or complex. Common vendor sources are listed in Table 13-9; databases in Table 13-10; and consumer sources in Table 13-11. Many consumer advocacy groups and their patient information resource materials can now be accessed through Internet searches. Table 13-11 lists some of the more germane Internet addresses.

**Mobility**

There are several types of mobility equipment. There are many items that help to facilitate ambulation. Canes and walkers are frequently used, with each offering a method of facilitating ambulation as well as enhancing ambulation safety. Prostheses or orthoses also are designed to assist in ambulation and mobility. (See Chapters 74–76, and 78 for additional details.)

Positioning adaptations and seating systems can range from the very simple to the intricate. Proper positioning provides the preliminary and necessary basis of posture for the teaching and development of other life skills. Good body support and head control are essential for many activities. Positioning can be simple, such as the placement of a wedge or

ADL, activities of daily living.

bolster. It also can involve elaborate seating configurations that require training for proper measurements and construction. The maintenance of skin integrity is another aspect of seating and positioning equipment that must be considered. As with adaptive devices, the more involved the seating requirements are, the more important it is to have representatives from occupational therapy and physical therapy with the physiatrist to formulate the seating requirements. (See Chapter 78 for additional information.)

Transfer equipment to facilitate a patient's movement from one place to another will depend on the amount of assistance required by the patient for the transfer. A transfer board is the simplest item of equipment for transfer. This is used to facilitate safe movement of the patient from a wheelchair to a bed, a chair, or an automobile. The less able the patient is to assist in the transfer process, the more elaborate or complex is the equipment

**TABLE 13.10 Databases and Resources for Rehabilitation****ABLEDATA**

Listings of assistive technology products and devices for people with disabilities and seniors. The database includes adaptations as follows: environmental, blind and low vision, deaf and hard-of-hearing, deaf blind, communication, computers, controls, education, housekeeping, orthotics, aids for daily living, prosthetics, recreational, safety and security, seating, therapeutic aids, transportation, workplace, walking, and wheeled mobility. Sponsored by the National Institute on Disability and Rehabilitation Research, U.S. Department of Labor.

**National Rehabilitation Information Center (NARIC)**

Maintains a research library of more than 65,000 documents and responds to a wide range of information requests, providing facts and referral, database searches, and document delivery. Through telephone information referral and the Internet.

NARIC disseminates information gathered from NIDRR-funded projects, other federal programs, and from journals, periodicals, newsletters, films, and videotapes. NARIC maintains REHABDATA, a bibliographic database on rehabilitation and disability issues, both in-house and on the internet. NARIC also prepares and publishes the annual NIDRR Program Directory, available in database format from NARIC's website. Services: Information and referral available by phone, email, fax, letter, website, and walk-in (free); document delivery is 5 cents per page (\$5 minimum), and 50 abstracts for \$5.

needed. Transfer equipment can be manually or electronically operated, and may require little or no exertion by the person being transferred or the person assisting in the transfer.

Wheelchairs are another category of mobility equipment and may be manually or electronically operated. (Wheelchairs are discussed further in Chapter 78.) The selection of the type of mobility aid will depend on the person's residual motor power to facilitate the process. Car and van adaptations, as well as community mobility in general, are discussed in Chapters 18 and 73.

## Communication

Augmentative and alternative communication systems are a major area of equipment provision. These devices are becoming increasingly more involved and more readily available. They range from low-tech communication boards and pointing devices through complex computer-based communication systems. The physiatrist should collaborate with an SLP and an occupational therapist in the selection of the optimal

augmentative communication system for the patient. The SLP would recommend the most appropriate device for communication. For the motorically challenged patient, the occupational therapist would recommend the most appropriate switch- and control-operated devices for the patient. The provision of adapted computer inputs is now an important area of consideration in the lives of people of all ages (79). (See Chapters 15 and 73 for additional information.)

## Environmental Management

Various adaptive devices are available to provide assistance in the home (80). Most of the devices are engineered for use in the kitchen. These can include one-handed cutting boards, one-handed sandwich holders, stove overhead mirrors for wheelchair-mobile people to see the top of the stove, and other items. Adaptations also are available for washer and dryer operation. Numerous devices are available for the bathroom to assist in independence and safety. Environmental controls for

home management are another example of assistive devices. Electronic Aids to Daily Living (EADLs), formerly known as environmental control units, can consist of a few simple devices (e.g., for turning on and off a light or television) or more elaborate systems that manage many of the electric functions in a home. These can be introduced in the rehabilitation unit environment (hospital-based EADLs) (79). (See Chapter 73 for additional details.)

Adaptations can also be made in the work environment to facilitate use by those requiring accommodations. Frequently, this is done on an individualized basis. If necessary, site visits are made to determine the needs for either adaptations or equipment. Considerations such as space needed for a wheelchair to turn or to pass through a door, and alterations of table position or height to a comfortable work level are examples of work adaptations.

**Leisure and Recreation**

People may want to pursue old hobbies or develop new leisure and recreational activities. Because of dysfunction, adaptations

of equipment required for an activity may be indicated. Just as with other previously described devices, coordination would be indicated for equipment provision. The therapeutic recreation specialist may assist in the identification of the leisure or recreational activity that a patient wants to pursue. The occupational therapist or orthotist may assist in the provision and fitting of the appropriate adaptation or splint needed to perform tasks involved in the activity of interest. (See Chapter 9 for additional information.)

**Resources**

Commercial vendors sell equipment and many adaptive devices (81). Most items can be used as purchased; others will need adaptations that customize the devices for the person. At other times, equipment will have to be individually designed and constructed to meet patient needs. These special items are done on an individual basis by bioengineering or orthotics with professional input from occupational or physical therapists or others.

There is wide variation in the cost of equipment, the requirements for documentation for procurement of equipment, and the availability of equipment for patient evaluation trials for efficacy. Some items, such as wheelchairs and EADLs, can be very costly to procure. Ideally, there would be a range of items available within each category (e.g., ADL, mobility, communication) that can be used for patient assessment or training, but often this is not economically feasible. Vendors sometimes can provide equipment for patient assessment and use. Equipment pools are another resource where equipment no longer needed by people or equipment shared among several facilities in an area can be used to assist in the evaluative and training process.

**Prescriptions for Devices**

Any device, be it a simple plate guard for eating or the most elaborately configured electric wheelchair, typically requires a physician prescription for insurance coverage, including Medicare. Even without insurance coverage, a physician's prescription often allows medically necessary devices to be purchased free of sales tax in many states. Those items that are considered durable medical equipment (DME) require specific information for prescription coverage. Not all items are DME. To avoid confusion and minimize patient expense, it is useful to provide a comprehensive equipment prescription for all medically necessary devices.

The patient's name and diagnosis are included in the information part of the prescription. Then the initial part of the prescription is the name of the item, the stock number or other identifiers, and, when appropriate, the source of the item. All parts, sizes, adaptations, colors, and so on, are included, as applicable. The justification and rationale for the item are included, as well as the estimated duration of use. A permanent need is documented as "greater than 12 months" for Medicare prescriptions. When expensive devices are being requested, it usually is necessary to receive approval from the third-party payer before ordering such equipment.

## DME Quality Control

Regardless of what adaptive equipment or device is ordered for a patient, there is a responsibility to ensure that the patient receives training in its use. Also, some items, such as wheelchairs, require fitting. Both the physician and the therapist requesting the equipment are responsible for ensuring that the equipment fits the patient and that the equipment received is operational for its intended purpose. This is especially true in managed-care settings, in which negotiated DME contracts may exist and determine what equipment is available. Timely follow-up is indicated for reassessment of the patient's use of the equipment and to ensure that the items serve the purpose for which they were initially ordered.

## CONCLUSION

The ability to comprehensively define the rehabilitation needs of the patient and to request specific, individualized, and appropriate therapeutic interventions distinguishes the physiatrist from all other medical specialties. To successfully identify and accomplish the goals of rehabilitation, the physical medicine and rehabilitation physician work closely with the allied health rehabilitation disciplines and other medical specialties. Referrals, orders, and equipment prescriptions are basic mechanisms by which the physiatrist requests the participation of the other professions in assessment, planning, and delivery of patient care. The necessary elements and specificity of detail included in the referrals or orders are largely determined by the mode of professional interaction and style of communication developed among the members of the rehabilitation team. A cohesive team with well-developed mechanisms for clear communication among its members can result in an approach to rehabilitation that exceeds the sum of its parts, a concept endorsed by the U.S. Department of Health and Human Services Agency for Health care Research and Quality (82). The rehabilitation medicine physician must be knowledgeable about the treatment strategies used and their potential interactions with the patient's medical problems. Providing appropriate therapy precautions is a particular responsibility of physiatrists. Effectively written referrals, orders, and equipment prescriptions will fully communicate patient needs, desired interventions, appropriate precautions, and expectations, and provide adequate mechanisms for feedback and quality control.

## ACKNOWLEDGMENT

Significant contributions were taken and modified from Chapter 1 by Joel A. DeLisa, Donald M. Currie, and Gordon M. Martin of the 3rd edition of this text as referenced, which also included substantial historical perspective not included here. The prior contributions, now revised, of coauthors to Chapter 13 of the 3rd edition of this text, Mary E. Heye and Mary Nelle Titus and the prior contributions, now revised, of coauthors to Chapter 46 of the 4th edition of this text, T. Russell Nelson, Thomas C. Turturro, and Alison J. Beck, are also acknowledged and appreciated.

# Psychological Aspects of Rehabilitation

This chapter begins by reviewing the history and current status of rehabilitation psychology. This is followed by a description of the direct and indirect services typically provided by rehabilitation psychologists. Frequently encountered psychological measures are described, and their importance for rehabilitation planning is stressed. The final section examines theories of adjustment to disability.

## REHABILITATION PSYCHOLOGY: HISTORY AND CURRENT STATUS

### History

Rehabilitation psychology is a specialty area within psychology that focuses on the study and application of psychological knowledge and skills on behalf of individuals with disabilities and chronic health conditions in order to maximize health and welfare, independence and choice, functional abilities, and social role participation (1). The field of rehabilitation psychology received initial impetus from veterans returning from the two world wars in the first half of the last century. Physical and occupational therapy trace their roots to World War I. After World War II, the Veterans Administration focused on the psychological needs of the physically disabled, which led to acceptance of psychologists as providers of mental health services. During this same time period, Howard A. Rusk developed the first comprehensive rehabilitation center, which led, with the leadership of others, to the development of physical medicine and rehabilitation as a medical specialty. Thus, the birth and maturation of the disciplines comprising the rehabilitation team have overlapping histories (2,3).

As the number of psychologists working in rehabilitation settings grew, the need for a professional forum arose. In 1949, a special-interest group within the American Psychological Association (APA) was created and in 1958 was granted division status. The Division of Rehabilitation Psychology of the APA provides leadership in formulating federal legislation and in various professional and lay organizations. The Rehabilitation Act of 1973 and the Education for All Handicapped Children Act of 1975 provided mandates for the participation of rehabilitation psychologists in services to the disabled (4). Rehabilitation psychologists promoted passage of the Americans with Disabilities Act of 1990 and its ongoing implementation (5). The injured veterans returning from the wars in Iraq and Afghanistan coupled with the aging population of the United States represent populations with needs that are uniquely addressed by rehabilitation psychologists.

### Current Status

Rehabilitation psychologists have struggled with their identity since the field's inception. Shontz and Wright argued for the distinctiveness of rehabilitation psychology (6). More recently, Glueckauf argued that rehabilitation psychology is subspecialty within the larger domain of health psychology. In this model, rehabilitation psychology is grouped with the subspecialties of clinical neuropsychology, geropsychology, and pediatric psychology (7). To promote this model, an Interdivisional Health Care Committee, with representatives from several divisions of the APA, was formed and continues to actively pursue a common agenda (8).

The identity problem of rehabilitation psychologists arises from the fact that they typically have doctoral degrees in clinical or counseling psychology and enter the field through internship training. A general degree program initially molds their professional identity rather than training in rehabilitation theories, principles, literature, and research; training that is available in only a select number of doctoral programs. Depending on the quality of internship and postdoctoral training, some practitioners may lack training in theoretical models of rehabilitation. There has been ongoing debate within the field of rehabilitation psychology about the "best" training model. The key area of disagreement relates to timing of specialized training (predoctoral vs. postdoctoral), with advocates for both points of view (9–13).

The training and practice of rehabilitation psychologists are changing for two reasons. First, the APA has developed a new model of education in which the graduate-level curriculum is generic, with specialization occurring through postdoctoral training. In 1995, the Division of Rehabilitation Psychology published guidelines for postdoctoral training in rehabilitation psychology (14). These guidelines define what constitutes comprehensive postdoctoral training of rehabilitation psychologists. A comprehensive revision of these guidelines based on the APA Board of Educational Affairs criteria is nearing completion and will be published in *Rehabilitation Psychology* (15,16). These guidelines will be posted to the Division of Rehabilitation Psychology Web site ([www.Div22.org](http://www.Div22.org)) when complete.

Stiers and Stucky (17) recently surveyed clinical training programs in rehabilitation psychology. Of the 117 sites identified, 94 responded to their survey. They found that the majority of sites did not have a complete rehabilitation focus to their clinical services and did not have faculty with specialty certification in rehabilitation. They found that there

were only 11 core fellowship sites that had a primary focus on rehabilitation psychology. They concluded that many patients and rehabilitation teams receiving services from psychologists in rehabilitation settings were receiving only partial benefit. They described the unmet needs in rehabilitation psychology training and argued for the development of a “tool kit” that provides standardized curricular materials and program evaluation tools. Second, the American Board of Rehabilitation Psychology (ABRP), [www.abrp.org](http://www.abrp.org), was established in 1995, with the first diplomate in rehabilitation psychology awarded in 1996. The ABRP provided a comprehensive rationale for specialty definition and competency-based practice standards (15,18). Those awarded the diplomate have typically completed postdoctoral training and are required to have 3 years of experience in rehabilitation psychology, two of which must be supervised. The ABRP is part of the American Board of Professional Psychology (ABPP), an organization of psychologists that accredits subspecialties, similar to the American Board of Medical Specialties for medical specialties.

The goal of the Division of Rehabilitation Psychology is to expand knowledge and seek solutions to problems related to disability and the rehabilitation process. The mission of the organization states:

*the Division of Rehabilitation Psychology will: (1) be APA's voice for the science and practice of psychology as it relates to changes in abilities and social roles arising from illness and disability, (2) be recognized by constituents internal and external to APA for the redefinition of “rehabilitation psychology” as an expanded spectrum of community and clinical services including prevention, rehabilitation, and postacute health care within the context of quality of life across the life-span, and (3) influence the health care marketplace such that rehabilitation psychology services are widely available and accessible and that the quality of life perspective counterbalances both the economic and the medical/curative approaches (19).*

The delivery of rehabilitation psychology services is adapting to the corporatization of health care and the reduction of expenditures in the Medicare and Medicaid programs (20–23). The impact of the Prospective Payment System (PPS) on rehabilitation psychologists is uncertain (24). Doctoral-trained rehabilitation psychologists can bill independently under Medicare Part B and, hence, are able to generate revenue in addition to the flat fee provided by the PPS. As a result, rehabilitation psychologists may assume expanded roles in patient evaluation and treatment planning. The shift to health maintenance and preferred provider organizations presents an evolving challenge, as payers are demanding psychological services that are brief, beneficial, and cost-effective. In response, rehabilitation psychologists are shifting their venues from hospitals to less expensive settings such as subacute and outpatient rehabilitation facilities, as well as to telehealth interventions (25). Wade and Wolfe edited a special section of the journal *Rehabilitation Psychology* which highlighted emerging approaches by pioneers in the field of telehealth and rehabilitation (26).

The importance of aiding the process of adjustment to disability and preventing secondary conditions was acknowledged by the addition of six current procedural technology (CPT) codes by the American Medical Association and their approval for reimbursement by the Medicare program. As of 2002, the new CPT codes for health and behavior assessment and intervention services apply to behavioral, social, and psychophysiologic procedures for the prevention, treatment, or management of physical health problems. These “Health and Behavior Codes” recognize psychology's role as a health care specialty and shift third-party reimbursement from a psychopathology model to a model focused on fostering individual adaptation and social accommodation. For example, CPT number 96152 pays for intervention services to modify the psychological, behavioral, cognitive, and social factors affecting health and well-being. For example, these services include using cognitive and behavioral interventions to initiate physician-prescribed diet and exercise programs. These codes also reimburse services such as patient adherence to medical treatment, symptom management, health-promoting behaviors, health-related risk-taking behaviors, and overall adjustment to physical illness. Federal reimbursement for these new codes will come from medical rather than from mental health funding and, hence, will not draw from limited mental health dollars. Recent passage of the Mental Health Parity Bill will enhance coverage of mental health services by eliminating the differential in co-payments between mental versus physical health services.

The paradigm shift by the World Health Organization and the National Institutes on Disability and Rehabilitation Research from a biomedical to a social model of disability bodes well for the continued relevance of rehabilitation psychology services and research (27–32). The International Classification of Functioning, Disability and Health (ICF) has been adopted by 191 countries as the international standard for classifying health and disability. As noted by Bruyere and Peterson (33), “the ICF represents a new way for the world to talk about health... The ICF is a classification system that uses a universal, culturally sensitive, integrative, and interactive model of health and functioning that is sensitive to social and environmental aspects of health and disability and covers the entire human life span.” The authors highlight that the concepts and assumptions that comprise the ICF reflect long-standing core values of rehabilitation psychologists including inclusion of and advocacy for people with disabilities in society.

The direct and indirect services described in the following section reflect services typically found within an inpatient medical rehabilitation setting. Similar services are provided in a suitably adapted manner on an outpatient basis. As service delivery shifts to outpatient and community settings, adaptations in these services continue to evolve. Despite the consolidation of health care payer and delivery systems, consumers continue to demand quality and value (34). The value of rehabilitation psychology services is acknowledged by the Commission on the Accreditation of Rehabilitation Facilities through their mandated availability of the rehabilitation psychologist as part of the

rehabilitation team in both acute and subacute rehabilitation facilities. Rehabilitation psychology's focus on enhancing the quality of life for those with chronic illness and disability remains the central goal despite changes in health care delivery paradigms. Expected changes in the health care delivery system will include universal coverage for all citizens with a focus on prevention, multidisciplinary health care team communication, and measuring outcomes (35,36). Rehabilitation psychology has a long-standing focus on recognizing and maximizing an individual's strengths and helping them to create a meaningful life despite being confronted with the challenges of living with a disability. Interestingly, a contemporary focus in the field of psychology is on "Positive Psychology." Positive psychology explores factors that make life worth living, enable people to successfully confront challenges, and facilitate extracting meaning from daily life (37–39). Dunn and Dougherty (40) argue for actively connecting rehabilitation psychology's foundations and existing strengths to the emerging field of positive psychology, thus enriching both fields of inquiry.

## DIRECT SERVICES

### The Clinical Interview

The psychologist's first contact with a patient is pivotal in the development of a therapeutic relationship and may occur before transfer to a rehabilitation unit. The psychologist may visit the patient before the initial interview to explain his or her role. The patient's expectations of meeting with the psychologist are determined by previous exposure to mental health professionals, communications from other team members, including the physician, and preliminary explanations from the psychologist. The patient's willingness to interact meaningfully with the psychologist can be strongly influenced by the physician. At the introduction, the psychologist will explain that comprehensive rehabilitation includes help with problematic thoughts and feelings associated with chronic illness or the onset of disability. Frequently, patients are relieved to discover that contact with the psychologist is a routine part of comprehensive rehabilitation.

The initial interview may last an hour or more. Patients with cognitive impairment may be seen only long enough for a general determination of their information-processing capacity and emotional state. Further assessment will await improvement in their cognitive status or contact with an informed family member. The length of the initial interview with non-cognitively impaired patients depends on the complexity of the medical or social issues. There are two major goals for the initial interview. First, a comprehensive history of the patient's social background is obtained. Table 14-1 lists frequently asked biographical questions. These data provide insight into previous learning experiences that may affect rehabilitation-related attitudes and behaviors. Second, the psychologist attempts to understand the disability as the patient sees it, with the most critical question being, what is the meaning of the disability for the patient and his or her life? The foundation for a meaningful

**TABLE 14.1** Psychosocial Information Sought During Initial Interview

Data on Family of Origin
Names, ages, occupations, marital status, and residence of parents and siblings
Religious training
Stability of family during early development
History of major mental disorder in immediate and extended family, including any history of sexual abuse, chemical dependency, suicide, or psychiatric hospitalization
Relevant Patient Information
Educational background and school achievement
Occupation and vocational history
Avocational activities and hobbies
History of adjustment to structured environments, such as school, work and military service
Social adjustment, including any previous arrests, chemical dependency treatment, or psychiatric diagnosis
Prior association with hospitals and health care
Preinjury stresses at the time of injury
Most difficult loss the patient has had to adjust to previously; success in that task
Prior associations with people who have a disability
Family Structure
Names, ages, and quality of relationship with spouse and children
Background of dating and sexual relationship with current spouse
Marital adjustment
Understanding the Patient's Perspective
The patient's understanding of the cause and probable course of the disability
The patient's initial thoughts at the onset of the disability (if traumatic)
The patient's most pressing immediate concern
How well the patient thinks he or she is coping with the situation
The patient's perception of how the disability will change lifestyle, including relationships, vocational future, and self-concept
The patient's understanding of the behavioral expectations in the rehabilitation unit compared with those in the acute-care unit of the hospital
The degree to which the patient's sense of self-esteem or employment is related to physique or physical skills
The patient's comfort in meeting with a psychologist
Techniques used to cope with stressful events in the past
Techniques used to get and maintain a sense of control over the environment

therapeutic relationship is laid, in part, by taking sufficient time to elicit the patient's perspective. The patient often faces a medical situation that he or she does not fully comprehend. Anxiety and fear often block the reception and communication of information between the patient and rehabilitation team members, especially physicians. The opportunity to have one's perspective, including cognitive and emotional aspects, aired in a supportive and clarifying manner is often therapeutic in

itself. As the U.S. population becomes older and more diverse, understanding the meaning of disability through the unique cultural background of the patient is imperative (41,42).

The psychologist occupies an unusually difficult position. Although a team member, the psychologist has the professional responsibility of maintaining the confidentiality of the therapeutic relationship. The patient may confide information that is personally sensitive and inappropriate to share with other team members. If directly asked by other team members about such information, the psychologist may have to explain that the information is confidential. Usually the patient is told that any information considered sensitive by the psychologist or so indicated by the patient will not be communicated to others. General information of a less sensitive nature is provided in the form of an initial interview note. Subsequent therapeutic contacts are recorded in the hospital chart or summarized periodically. The frequency of these contacts depends on the goals established during the initial interview, the current degree of psychological distress, the potential for behavioral decompensation, concerns expressed by other team members, and staffing levels.

### Standardized Assessment

Given the time-consuming and subjective nature of clinical interviews, rehabilitation psychologists use standardized tests to speed assessment and enhance interventions (43,44). This section describes several frequently used instruments. Standardized measures of personality, mood, intellectual ability, and academic achievement are briefly discussed. The domains of neuropsychological and chemical use assessments are covered in more detail.

### Personality

A personality test conventionally refers to a measure of personal characteristics such as emotional status, interpersonal relations, motivation, interests, and attitudes. Personality inventory development has generally relied on one or more methods including content validation, empirical criterion keying, factor analysis, and personality theory. Personality measurement has generated controversy over two issues. The first concerns the stability of personality traits across situations as opposed to the situational specificity of behavior (45). The second issue involves the degree to which a given personality characteristic reflects a merely transitory state rather than a stable underlying trait. Anastasi and Urbina (46) provided a thorough overview of these issues and of other psychological measurement concepts including norms, item analysis, reliability, and validity. Elliott and Umlauf (47) caution that the insensitive use of personality measures with individuals who have medical symptoms or limited physical abilities can produce misleading results. Johnson-Greene and Touradji (48) provide a contemporary review of the role of personality in rehabilitation outcomes and adjustment to disability. The most frequently used personality inventory designed to measure psychopathology is the Minnesota Multiphasic Personality Inventory-2 (MMPI-2) that is now available in a new form entitled the

Minnesota Multiphasic Personality Inventory-2 Restructured Form (MMPI-2-RF). Two personality measures of nonpathologic or “normal” personality relevant to rehabilitation are the Revised NEO Personality Inventory (NEO-PI-R) and the Strong Interest Inventory (SII).

### *Minnesota Multiphasic Personality Inventory-2*

The MMPI-2 is the revised version of the MMPI, the most widely used and thoroughly researched objective measure of personality (49–53). The MMPI-2 is composed of statements describing thoughts, feelings, ideas, attitudes, physical and emotional symptoms, and previous life experiences. In general, the material included on the MMPI-2 is usually covered in a clinical interview. However, factors of privacy, time-savings, and the clinical relevance of the items have ensured its acceptance in health-care settings.

The MMPI-2 was originally designed to yield information about personality factors related to the major psychiatric syndromes. The 567 true-false questions are grouped into ten clinical scales (Table 14-2) that continue to reflect important aspects of personality despite their obsolete psychiatric titles. The items composing each scale were determined statistically. An item was included only if a carefully diagnosed group of patients (e.g., those hospitalized for depression) answered that question in a manner statistically different from that of other carefully diagnosed groups of patients (e.g., schizophrenics) and from the normal standardization sample. The MMPI-2 standardization sample consisted of 2,600 persons from several states chosen to reflect several national census parameters, including minority group status. This system of item selection (i.e., empirical criterion keying) fostered the inclusion of subtle items, items that make the MMPI-2 less easily faked when compared with other personality measures.

The ten clinical scales are interpreted with the aid of four validity scales (see Table 14-2). These scales provide information on the client's response style such as literacy, cooperation, malingering, comprehension, and defensiveness. The empirical nature of the inventory has permitted construction of special scales. For example, there are scales to help predict rehabilitation motivation, headache proneness, and tendencies toward the development of alcoholism. Additionally, there are extensive MMPI norms on persons with specific diagnoses such as multiple sclerosis and spinal cord injury (SCI) (54). Norms are reported as standard scores with a mean of 50 and a standard deviation of 10. A score of 65 or greater is the point at which the normal and the pathologic groups are most reliably discriminated. However, depending on the scores obtained on the validity scales, this “cut-score” may be adjusted by the trained interpreter.

The MMPI-2 requires an eighth-grade reading level and is intended for adults 18 years of age and older. A version of the MMPI entitled the MMPI-A is intended for use with adolescents (55). The MMPI-2 requires about 90 minutes to complete. Although many computerized scoring services are available, this does not obviate the need for interpretation by an experienced psychologist. A variety of factors—including

**TABLE 14.2** Brief Description of the Minnesota Multiple Personality Inventory-2: Validity and Clinical Scales

Scale		Number of Items	Elevated Scores Suggest
Number	Name		
Q	Cannot say	567	A large number of items have not been answered, a possible indication that the patient is resentful or is uncomfortable with ambiguity
L	L scale	15	An effort to create the impression of being a person with high moral, social, and ethical values
F	F scale	60	The questionnaire has been invalidated by some factor, including lack of comprehension, poor reading ability, mental confusion, a deliberate desire to fake psychiatric difficulty, random marking of responses, or scoring errors
K	K scale	30	A self-view of being well adjusted, capable, and confident, which, at higher scale elevations, is likely to represent a denial of the true state of affairs
1	Hypochondriasis	32	Undue concern with bodily states and preoccupation with possible symptoms of physical illness
2	Depression	57	Depression, sadness, pessimism, guilt, passivity, and tendency to give up hope easily
3	Hysteria	60	Psychological immaturity, self-centeredness, superficial relationships, and frequent use of denial in everyday life, and a tendency to develop physical symptoms under stress
4	Psychopathic deviate	50	Assertiveness and nonconformity at moderate elevations; angry rebelliousness and noncompliance with social mores at extreme levels
5	Masculinity-femininity	56	The degree of identification with roles and interests traditionally assigned to the sex opposite that of the respondent
6	Paranoia	40	Interpersonal oversensitivity and irritability about motives or behavior of others, and at extreme elevations, suspicious thinking similar to that of people with paranoid personality traits
7	Psychasthenia	48	General feelings of anxiety, with excessive rumination about personal inadequacies
8	Schizophrenia	78	Feelings of detachment from the social realm, extending to frank mental confusion and interpersonal aversiveness
9	Hypomania	46	Talkativeness, distractibility, physical restlessness, and, at times, impatience, irritability, or rapid mood swings
0	Social introversion	69	Social introversion and a lack of desire to be with others

race, socioeconomic status, unique family circumstances, ethnic background, and physical disability—may distort the MMPI-2 profile (56).

An important goal in the development of the MMPI-2 was to preserve sufficient item continuity with the original MMPI to allow for the generalizability of the voluminous MMPI research literature to the MMPI-2. Unfortunately, Humphrey and Dahlstrom reported that profiles generated by the MMPI and the MMPI-2 on the same subjects are too frequently at variance to be able to consider the two instruments interchangeable (57). Hence, it would be an error to assume that the MMPI clinical research literature can be uncritically generalized to the MMPI-2 for all patients. Moreover, many of the original criticisms of the MMPI remain problematic for the MMPI-2 (58). In particular, the MMPI was originally written to aid physicians in the medical management of patients who were believed to have psychological factors

intertwined with their presenting complaints. MMPI and MMPI-2 normative studies on medical patients (59) consistently reveal elevations of three to six points on clinical scales 1, 2, and 3 when compared to the MMPI normative samples. Appropriate interpretation of the MMPI-2 with medical and rehabilitation patients requires knowledge of these normative biases (60).

### ***Minnesota Multiphasic Personality Inventory-2 Restructured Form***

The MMPI-2-RF represents the continuing evolution of the MMPI (61). The original ten MMPI clinical scales were problematic because of their intercorrelations, item overlap, and heterogeneous item content. To address these problems, a set of nine Restructured Clinical Scales (RCS) was derived (Table 14-3) by identifying the major distinctive “core” components of each clinical scale. Tellegen et al. (62) provided

**TABLE 14.3** Brief Description of the Minnesota Multiple Personality Inventory-2: Restructured Clinical Scales

Scale		Number of Items	Elevated Scores Suggest
	Name		
RCd	Demoralization (dem)	24	General emotional turmoil, with feelings of discouragement, demoralization, poor self esteem, pessimism, depression, anxiety and somatic complaints
RC1	Somatic Complaints (som)	27	Somatic preoccupation with a large number of physical complaints, resistance to considering that psychological factors are related to physical symptoms
RC2	Low Positive Emotions (lpe)	17	Lack of positive emotional engagement in life, unhappy, pessimistic, demoralized, low energy, feelings of helpless and hopeless, introverted, passive and withdrawn
RC3	Cynicism (cyn)	15	That other people are seen as untrustworthy, uncaring, and exploitative
RC4	Antisocial Behavior (asb)	22	A history of antisocial attitudes and behaviors, difficulties conforming to societal norms, increased risk of substance abuse, aggressive behavior and argumentativeness
RC6	Ideas of Persecution (per)	17	Persecutory thinking with feelings of being targeted, controlled, and suspicious of others
RC7	Dysfunctional Negative Emotions (dne)	24	A tendency to experience anxiety and depression with feelings of insecurity, intrusive thoughts, ruminations, brooding and submissive in relationships
RC8	Aberrant Experiences (abx)	18	The presence of sensory, perceptual, cognitive, and motor disturbances suggestive of psychotic disorders
RC9	Hypomanic Activation (hpm)	56	Thought racing, high energy, heightened mood, irritability, aggressiveness, and poor impulse control

data documenting the improved psychometric properties of the RCS that included improved reliability, reduced scale intercorrelations, and improved convergent and discriminant validity. Once the RCS were devised, 23 additional specific problem scales were constructed that reflected distinctive components of the old clinical scales that were not captured in the new scales with titles such as malaise, suicidal/death ideation, anger proneness, substance abuse, shyness, and ideas of persecution. In addition, the MMPI-2-RF has a total of eight validity scales and three higher order scales, entitled emotional/internalizing dysfunction, thought dysfunction, and behavioral/externalizing dysfunction. The MMPI-2-RF has a total of 338 items and 50 empirically revised scales. The MMPI-2-RF requires 35 to 50 minutes to complete and is written at a sixth-grade reading level.

### ***NEO Personality Inventory Revised***

The NEO Personality Inventory Revised (NEO-PI-R) reflects the culmination of decades of personality research that concludes that personality traits can be summarized in terms of the so-called five-factor model (63,64). The NEO-PI-R was designed to measure the five major dimensions or domains thought to be central to normal adult personality. These dimensions are entitled Neuroticism (N), Extraversion (E), Openness (O), Agreeableness (A), and Conscientiousness (C). Each domain scale has six facet scales resulting in a total of 35 scales on the inventory. Neuroticism refers to a general

tendency to experience negative affect, self-consciousness, poor coping, irrational ideas, feelings of vulnerability, and difficulties controlling cravings and urges. Extroversion relates to interpersonal warmth, gregariousness, assertiveness, activity, excitement seeking, and the tendency to experience positive emotions. Openness pertains to depth of imagination, aesthetic sensitivity, intensity of feelings, preference for variety, intellectual curiosity, and independence of judgment. Agreeableness includes the characteristics of trust, straightforwardness, altruism, methods of handling interpersonal conflict, humbleness, and sympathy for others. Finally, conscientiousness encompasses the characteristics of competence, organization, reliability, achievement striving, self-discipline, and deliberation before acting.

NEO-PI-R item construction was based on rational-theoretical methods. Item selection was determined by internal consistency and factor analytic data. The scale's 240 items are rated on a five-point continuum from "strongly disagree" to "strongly agree." The inventory is designed for adults, 17 years of age and older. The inventory requires a sixth-grade reading level and about 45 minutes for completion. There are separate adolescent norms for those less than 21 years old. The NEO-PI-R has a self-report (Form S) and an observer rating form (Form R). This dual-form feature is unique among personality measures and is especially relevant to rehabilitation research. Also noteworthy, the NEO-PI-R items do not contain references to physical abilities or sensations that might distort a physically disabled subject's responses.

The NEO-PI-R is a reliable and valid measure. Validity has been established through numerous studies that correlate the NEO-PI-R with other measures of personality. All these correlations have been in accord with theory and expectation (65). There are two limitations to the NEO-PI-R. The NEO-PI-R assumes an honest respondent; no subtle items or validity scales are provided. In addition, it remains unclear to what degree the subject's current mood (state) may impact the response to test items that describe long-standing personality characteristics (trait).

The NEO-PI-R has been used in a number of rehabilitation studies. Rohe and Krause administered the initial version of the NEO-PI-R to males with traumatic SCI 16 years after injury (66). The subjects scored lower on the scales of conscientiousness, assertiveness, and activity; they scored higher on the scales of excitement seeking and fantasy when compared with the adult male normative sample. Scales reflective of negative affect were not elevated. The subjects' reduced conscientiousness and non-elevated neuroticism scale scores have negative implications for adherence to rehabilitation regimens but positive implications for long-term coping abilities. A subsequent study on the same sample correlated personality and self-reported life adjustment. Rohe and Krause discovered that elevated scores on the depression scale were associated with poorer outcomes, whereas elevated scores on the scales dealing with warmth, positive emotions, actions, and values were associated with superior outcomes. The authors suggested that personality assessment may be an invaluable aid in predicting long-term outcomes and can help delineate those individuals most vulnerable to negative outcomes, perhaps indicating a need for more careful follow-up and supportive services for this subgroup (67). In a seminal study using the NEO-PI-R, the authors assessed whether SCI is associated with personality change by comparing the personality test scores of identical twins, one of whom sustained an SCI. The authors found no significant differences between the NEO-PI-R scores of the twins with SCI and their non-SCI twins (68).

### ***The Strong Interest Inventory***

The SII is traditionally considered a measure of vocational interests; however, research has supported its use as a valid non-pathology-oriented measure of personality (69). First published in 1927, the SII is one of the most thoroughly researched, highly respected, and frequently used psychological tests. The SII was revised in 2004. Improvements include more focus on business and technology occupations, number of items reduced from 317 to 291, representative sampling of ethnic, racial, and demographic workforce diversity, and an expanded number of scales. The SII asks the respondent to indicate their level of interest on a five-point Likert scale ranging from strongly like to strongly dislike for occupations, subject areas, activities, leisure activities, and people. The last section asks the respondent to rate their possession of nine personal characteristics. The test requires 35 to 40 minutes to complete and is written at an eighth- to ninth-grade reading level (70).

The General Occupational Themes, one of the four types of scales on the SII, are based on trait theory as derived by Holland (71). Holland drew on factor-analytic studies of personality and

interests to produce a typology of six basic personality types. These types are titled realistic, investigative, artistic, social, enterprising, and conventional. Rohe and Athelstan administered the SII to a national sample of persons with SCI (72). Contrary to previous research, they found unique personality characteristics associated with persons having SCI of traumatic onset. These characteristics included an interest in activities requiring physical interaction with things, such as machinery, and a disinterest in activities that require intense or complex interaction with either data or people. Malec used the Eysenck Personality Inventory with people having SCI of traumatic onset and discovered a pattern of personality characteristics congruent with that found in Rohe and Athelstan's study (73).

Rohe's review of the literature suggested that when a disability is of traumatic onset and secondary to the individual's behavior, statements in the literature about the lack of a relationship between disability and personality characteristics appear to be inaccurate (74). He noted that the previous literature either used pathology-oriented measures (e.g., MMPI) or studied individuals whose disability was not the result of trauma associated with their behavior. An additional study sought to determine if those personality characteristics associated with people having SCI would change after years of living with the disability. The data indicated that personality characteristics remained constant over an average of ten years (75). Rohe and Krause conducted a follow-up study to the aforementioned personality stability study. They found that males with traumatic SCI displayed marked consistency in personality characteristics over an 11-year follow-up period (76).

The MMPI-2, MMPI-2-RF, NEO-PI-R, and SII represent four measures of personality relevant to clinical rehabilitation settings. These measures can help answer diagnostic and management questions. For example, a patient's unwillingness to comply with requested medical interventions or the structure imposed by the hospital environment may be discerned with the use of personality measures. Knowledge of such personality characteristics can help prevent ill-advised interventions and can create a treatment environment designed to maximize patient compliance. While clinical experience attests to the usefulness of such assessment, systematic empirical research on this topic is a pressing need.

### **Mood**

Problematic mood, especially depression, in patients is one of the most common concerns among rehabilitation team members and a frequent reason for psychological assessment. Depression is an imprecise term used to describe an affective state that ranges from "being down" to major depressive disorder (MDD). The incidence and prevalence of MDD in rehabilitation populations has been the focus of significant research and debate. Assessing depression immediately after disability onset is complicated by such medical and environmental factors as sleep disruption, pain, and decreased appetite. Two brief, psychometrically robust and helpful instruments are the Patient Health Questionnaire-9 (PHQ-9) (77) and the Beck Depression Inventory-Fast Screen (BDI-FS).

**TABLE 14.4 PHQ-9 Items**

Over the *last 2 weeks*, how often have you been bothered by any of the following problems?  
Response options: (0) not at all, (1) several days, (2) more than half the days, (3) nearly every day

1. Little interest or pleasure in doing things.
2. Feeling down, depressed, or hopeless.
3. Trouble falling or staying asleep, or sleeping too much.
4. Feeling tired or having little energy.
5. Poor appetite or overeating.
6. Feeling bad about yourself—or that you are a failure or have let yourself or your family down.
7. Trouble concentrating on things, such as reading the newspaper or watching television.
8. Moving or speaking so slowly that other people could have noticed? Or the opposite—being so fidgety or restless that you have been moving around a lot more than usual.
9. Thoughts that you would be better off dead or of hurting yourself in some way.

Reprinted from the PRIME-MD® Patient Health Questionnaire.  
©1999, Pfizer Inc.

### ***Patient Health Questionnaire-9***

The PHQ-9 is a brief, nine-item measure whose item content parallels the Diagnostic and Statistical Manual of Mental Disorders, Fourth Edition (DSM-IV) (78) criteria for major depression (Table 14-4). The PHQ-9 was developed for medical patients with high rates of nonspecific physical symptoms. Although the PHQ-9 contains somatic items that might confound accurate diagnosis, the clinician reviews the responses to ensure that any positive somatic responses are not due to medically based symptoms or normal bereavement. Bombardier et al. (79) studied the PHQ-9 with an SCI sample 1 year post injury. The average score was 5.48, with 11.4% of the sample meeting the criteria for probable MDD with a mean score of 18.1. The PHQ-9 appears to be a promising instrument for detecting MDD in rehabilitation populations.

### ***Beck Depression Inventory-Fast Screen for Medical Patients***

The BDI-FS for medical patients (80) is a self-report inventory that screens for depression in adults and adolescents. The items were extracted from the original 21-item Beck Depression Inventory-II (81) and focus on the cognitive and affective components of depression, systematically excluding the somatically focused items. The BDI-FS consists of seven groups of four statements. The item groupings focus on sadness, pessimism, past failure, loss of pleasure, self-dislike, self-criticalness, and suicidal thoughts. A score of 4 falls in the mildly depressed range while a score of 8 is average for persons with MDD. The inventory requires 5 minutes to complete and has acceptable reliability and validity data. The correlation between the 7-item and the 21-item inventories is 0.91. A recent study using the

BDI-FS with persons with multiple sclerosis supported its concurrent and discriminative validity (82).

### ***Intellectual Ability***

Intellectual ability tests provide a summary score that serves as a global index of a person's general problem-solving ability, frequently referred to as an IQ or intellectual quotient score. This summary score is validated against a broad criterion such as scholastic achievement or occupational success. Although such tests are constructed of a number of subtests that sample facets of intellectual functioning, they are usually weighted toward tasks requiring verbal ability. The most frequently encountered measure of intellectual ability is the Wechsler Adult Intelligence Scale, III (WAIS-III) (83).

### ***Wechsler Adult Intelligence Scale, III***

The WAIS-III is the second revision of the WAIS originally published in 1955. The WAIS-III was standardized on a normative sample of 2,450 "normal adults" from ages 16 to 89, divided into 13 age groups. They were chosen to be representative of the US population as determined by the 1995 census update. The sample was stratified by gender, educational level, ethnicity, and region of the country. On the WAIS-III, items from earlier versions of the test that had become obsolete because of societal changes or bias against ethnic groups were altered or eliminated and the artwork was updated. Other improvements include extending the range of possible scores both downward and upward (full-scale IQ range = 45 to 155), decreased reliance on timed tests, and addition of a new subtest that requires conceptual reasoning using abstract symbols (matrix reasoning). The WAIS-III must be administered by a trained examiner and requires 75 to 90 minutes for completion.

The WAIS-III consists of 14 subtests, one of which is optional. Table 14-5 lists in their order of administration these subtests and what they measure. On the WAIS-III, six subtests are used in the computation of the verbal IQ, and five subtests determine the performance IQ. In general, the WAIS-III has deemphasized speed of responding by reducing the number of items with time bonus points, eliminating the picture arrangement subtest, and replacing the timed object-assembly subtest with the nontimed matrix reasoning subtest. Object assembly remains available when time and motoric response capabilities are not an issue. All WAIS-III subtest scores are corrected for age and standardized with a mean of 10 and a standard deviation of 3. The full-scale IQ is calculated by averaging scores obtained from the verbal and performance IQs.

The WAIS-III incorporates earlier research of Cohen, who discovered that three underlying factors accounted for most of the WAIS-R test variance (84). The Cohen factors are now codified as three of the four WAIS-III "index scores." The names of the index scores and the subtests used to compute them are *verbal comprehension* (vocabulary, similarities, information), *perceptual organization* (picture completion, block design, matrix reasoning), *working memory* (arithmetic, digit span, letter-number sequencing), and *processing speed* (digit symbol-coding, symbol search). As with the traditional IQ

**TABLE 14.5** The 14 Subtests of the Wechsler Adult Intelligence Scale-III

Test		Number of Items	Task	Measures
Number	Title			
Verbal Scale				
2	Vocabulary	35	Define the meaning of words presented both orally and visually	Verbal and general mental ability
4	Similarities	14	Explain the way in which two things are alike	Verbal concept formation
6	Arithmetic	14	Solve arithmetic problems presented in a story format without using pencil or paper	Concentration and freedom from distractibility
8	Digit span		Listen to and orally repeat increasingly long lists of numbers, with separate lists presented in forward and reverse directions	Ability to attend; immediate auditory recall
9	Information	29	Answer oral questions about diverse information acquired through living in the United States	Retention of long-term general knowledge
11	Comprehension	16	Explain what should be done under certain circumstances and why certain social conventions are followed; interpret proverbs	Common sense, abstract reasoning, and social judgment
13	Letter-number sequencing <sup>a</sup>	7	Order sequentially a series of numbers and letters initially presented in a specified, random order	Working memory and attention
Performance Scale				
1	Picture completion	20	Determine which part is missing from a picture of an object or scene	Visual recognition, remote memory, and general information
3	Digit symbol-coding		In a timed code substitution task, pair nine symbols with nine digits	Concentration and psychomotor speed
5	Block design	9	Reproduce a two-dimensional design on a card by using 1-inch block whose sides are red, white, or red and white	Visuospatial organizing ability
7	Matrix reasoning	26	Continuous and discrete pattern completion, classification, reasoning by analogy, serial reasoning	Visual information processing and abstract reasoning skills
10	Picture arrangement	10	Arrange sets of cards containing cartoon-like drawings so that they tell a story	Social judgment, sequential thinking, foresight and planning
12	Symbol search <sup>a</sup>	60	Visually scan a target group and a search group of symbols, then indicate whether the target symbols appear in the search group	Visual scanning and divided visual attention
14	Object assembly <sup>b</sup>	4	Properly arrange four cut-up cardboard figures of familiar objects	Visual concept formation and visual

<sup>a</sup>Supplementary subtest.<sup>b</sup>Optional subtest.

scores, index scores have a mean of 100 and a standard deviation of 15. They are sometimes reported in lieu of the traditional IQ scores. The subtests of digit symbol coding and symbol search were added to the WAIS-III to measure the proposed fourth factor, *speed of information processing*, as suggested by Malec et al. (85). The test exceeds all standards of reliability and validity. Reviewers have been uniformly impressed with the quality of the resulting instrument (86,87). The WAIS-IV was published in late 2008 (88). This new version has reduced emphasis on motor demands and timed performance, enlarged visual

stimuli, reduced testing time, updated norms, and improved psychometric properties. Many of these improvements reflect specific requests by rehabilitation psychologists working with populations who have compromised sensory and motor functions.

Given the emotional significance of IQ scores, psychologists usually convert both IQ scores and discussions about them into either percentiles or classifications (Table 14-6). When the physician is confronted with questions about test results from patients, the use of either percentiles or classifications

**TABLE 14.6 IQ Scores, Percentile Ranges, and Classifications for the Wechsler Adult Intelligence Scale-III**

IQ Score	Percentile Range	Classification
130 and above	98 or greater	Very superior
120–129	91 to 97	Superior
110–119	74 to 89	High average
90–109	25 to 73	Average
80–89	9 to 23	Low average
70–79	2 to 8	Borderline
69 and below	< 2	Extremely low

is recommended. Measures of intellectual ability help the physiatrist set appropriate expectations about the rate and complexity of learning legitimately expected from the patient. They also serve as the cornerstone for determining the presence of organic brain dysfunction and provide guidance for post-dismissal vocational planning.

### Academic Achievement

A frequently overlooked but nonetheless important factor within rehabilitation settings is academic achievement. Reading and mathematics achievement are of particular concern not only during inpatient rehabilitation but also for longer-range educational and vocational planning. The patient's reading level is a potential limiting factor in tasks ranging from filling out hospital menus to incorporating ideas presented in patient education materials. The average reading level in the United States is at the sixth grade, the level required to read a newspaper. Patient education materials, however, often reflect the reading levels of the professionals who devise them. As the patients' reading level falls below the national average, progressively greater reliance on oral instruction and audiovisual materials becomes necessary. Patients are often expected to use mathematics when recording fluid intake and taking correct dosages of medications. Two frequently used measures of reading and mathematical achievement are the Wide Range Achievement Test-4 (WRAT-4) and the Woodcock-Johnson Psycho-Educational Battery-III.

### Wide Range Achievement Test-4

The WRAT-4 is the current edition of the WRAT (89). The test provides assessment of reading, spelling, and mathematics achievement. Reading achievement is based on the subtests Word Reading and Sentence Comprehension. The Word Reading subtest requires correct pronouncement of single words. The Sentence Comprehension subtest requires that the subject demonstrate understanding of the sentence by supplying one or two words that completes the meaning of the sentence. These two subtests yield a reading composite score. The addition of the Sentence Completion subtest effectively addressed the criticism that the WRAT-4 was not truly measuring reading achievement. The Spelling test requires correct spelling of

words presented by the examiner in the context of a sentence. Mathematics achievement has two subtests entitled Oral Math and Mathematics Computation. The Math Computation subtest is administered to children aged 8 and older and ranges from simple addition to algebra. The Math Computation subtest has a time limit of 15 minutes. The WRAT-4 is for individuals from 5 through 94 years of age. There are alternate forms, entitled "Blue" and "Green." The entire test can be administered in 30 to 45 minutes, and results are presented in the form of standard scores, percentiles, stanines, grade equivalents and Rasch ability scaled scores. The WRAT-4 is reliable, and the stratified national sample of 3,000 individuals is representative of the U.S. population in terms of age, gender, ethnicity, geographic region, and educational attainment.

### Woodcock-Johnson Psycho-Educational Battery-III

The Woodcock-Johnson Psycho-Educational Battery-III (WJ-III) contains 42 subtests subdivided into two parts: cognitive ability (20 subtests) and academic achievement (22 subtests). The WJ-III replaces the Woodcock-Johnson-Revised, which received critical acclaim for ease of administration, reliability, validity, and normative sampling procedures. Improvements of the current version include expanding the number of subtests, co-norming the cognitive ability and the academic achievement tests on a large nationally representative sample of 8,818 subjects from 100 geographically diverse U.S. communities, providing age norms from 2 to more than 90 years, and decreasing testing time through focusing testing at the subject's ability level. Efforts were made to minimize the use of manipulatives and eliminate items that might be culturally insensitive to individuals with disabilities. Both improvements are helpful when assessing those with disabilities (90).

The academic achievement subtests are grouped into five broad curricular areas: reading, oral language, mathematics, writing, and academic knowledge. The achievement tests are further organized into groupings that aid interpretation. Reading achievement is determined by averaging three subtests requiring about 15 minutes to complete. These three subtests assess letter-word identification, reading fluency, and passage comprehension. Thus, the resulting score reflects diverse aspects of reading including reading decoding, reading speed, and reading comprehension. Achievement scores are reported in age- and grade-normed percentiles, and reading ranges from easy to difficult. Mathematics achievement is based on three subtests consisting of calculation, math fluency, and applied problems that require about 20 minutes to complete. The three remaining achievement clusters are of less relevance to inpatient rehabilitation but may be useful in post-dismissal planning. The WJ-III is an exceedingly well-constructed test and has become the standard to which other tests of ability and achievement are compared. The cognitive test portions of the WJ-III can serve as an alternative to the WAIS-III when a broad-based, well-constructed measure of intellectual ability is desired (91,92). The WJ-III Normative Update (WJ-III NU) provides updated norms based on the 2005 United States Census Projections. The WJ-III NU renews and refines the validity of both the cognitive and achievement subtests,

providing contemporary norms for an ever-changing U.S. population (93).

### **Neuropsychological Assessment**

Individuals with cognitive dysfunction represent one of the largest groups receiving rehabilitation services. For many, the deficits are transient. For some, cognitive deficits are permanent and not only will complicate the learning of independent living skills but also will determine future living arrangements, social interactions, and vocational prospects. In both situations, the rehabilitation psychologist is frequently asked to clarify the nature and type of cognitive deficits. This section describes three helpful screening tests of cognitive status entitled the Montreal Cognitive Assessment (MoCA), the Galveston Orientation and Amnesia Test (GOAT), and the Repeatable Battery for the Assessment of Neuropsychological Status (RBANS). Next, two approaches to neuropsychological assessment—the quantitative approach, as exemplified by the Halstead-Reitan Neuropsychological Battery (HRNB), and the qualitative approach, as exemplified by the Boston Process Approach—are described.

### **Screening Measures of Cognitive Status**

The physician frequently encounters patients of doubtful potential for a rehabilitation program. A question that often arises is whether the patient shows evidence of organic brain dysfunction. Mental status scales can be divided into three groups: lengthy scales with multiple content, abbreviated scales with one or two items per cognitive area, and short scales of ten or fewer items. Lengthy scales often require 1 hour to administer and may not provide enough information to warrant the time required. Short scales tend to focus on orientation questions, ignoring the diversity of cognitive abilities. Nasreddine et al. devised the MoCA to generate helpful information in a minimum of time (94).

### **The Montreal Cognitive Assessment**

The MoCA is the first brief screening measure specifically designed to detect mild cognitive impairment (MCI). MCI is conceptualized as an intermediary state between normal cognitive aging and dementia (95). Although the Mini-Mental State Examination (MMSE) remains in frequent use (96), there have been many criticisms of the measure, including its lack of sensitivity to MCI (97). The MoCA was derived from observation of cognitive domains frequently impacted in those with MCI. The MoCA is a one page, 30-point instrument that requires 10 minutes to administer. The MoCA tasks include five-item verbal learning and delay recall, clock drawing, cube copy, alphanumeric sequencing, phonemic fluency, verbal abstraction, sustained attention on a tapping task, serial subtraction, digits forwards and backwards, three-item confrontation naming, sentence repetition, and orientation to time and place. The MoCA was found to have high sensitivity and specificity for detecting MCI. When compared to the MMSE on samples of patients with Parkinson's disease and memory impairment, the MoCA was found to be a superior instrument

(98,99). The MoCA is available for free ([www.mocatest.org](http://www.mocatest.org)) and has been translated into 17 languages. Persons scoring: 26 or higher are in the non-impaired range, 26 to 21 are in the MCI range, and below 21 are in the Alzheimer's disease range. The MoCA has much to offer the rehabilitation inpatient setting where rapid and reliable screening for subtle cognitive dysfunction is frequently requested.

### **The Galveston Orientation and Amnesia Test**

The GOAT was developed by Levin et al. (100) and measures amnesia and disorientation after head injury. The scale consists of ten questions that focus on temporal orientation, recall of biographical data, and memory of recent events. The patient can obtain a maximum of 100 points; the final score is computed by subtraction of the number of error points. The GOAT was standardized on a group of 50 young adults (median age 23) who had recovered from mild closed head injury, usually consisting of a momentary loss of consciousness. Scores below those received by all members of the control group (<65) are designated impaired; scores between 66 and 75 are designated borderline; and those above 75 are considered normal. The greatest scoring difficulty occurs where points are assigned for the patient's accuracy in recalling events before trauma. More recently, Bode et al. (101) rescored the items as dichotomies and identified three strata of posttraumatic amnesia (PTA). Equal-interval measures of PTA were created, and a self-scoring key was developed to assess PTA more efficiently. PTA is defined as the time during which the GOAT score is 75 or less. Validity data were generated by a comparison of the length of the PTA with the variables of initial neurologic impairment and scores on the Glasgow Outcome Scale. In both cases, the GOAT score readily discriminated according to the severity of head injury. Scaling recovery of cognitive function in the noncomatose patient permits meaningful discussion with the family and rehabilitation team members. Most important, attempts at more involved neuropsychological assessment usually prove non-productive until the patient consistently obtains scores of 70 or greater. Once a score of 70 is achieved, neuropsychological test data usually are reliable for further rehabilitation and postdischarge planning.

### **The Repeatable Battery for the Assessment of Neuropsychological Status**

The RBANS is a recently developed, brief battery that fills an important niche between brief screening measures of cognitive status and comprehensive neuropsychological assessment. The RBANS is an individually administered instrument designed to measure attention, language, visuospatial-constructional abilities, and immediate and delayed memories (102). The test requires about 30 minutes to complete. The RBANS is intended for use with adults between 20 and 89 years. Norms are based on a stratified, nationally representative sample of 540 healthy adults. The RBANS subtests are subdivided into five cognitive domains: immediate memory, visuospatial reasoning, language, attention, and delayed recall. A total scale score is

also generated. The 12 subtests are entitled *list learning, story memory, figure copy, line orientation, picture naming, semantic fluency, digit span, coding, list recall, list recognition, story recall, and figural recall*. An alternate form is available. The test is a collection of item types from other well-known tests that are used to assess memory and cognitive function. Although there are some limitations to the depth of the test manual and associated data, the RBANS has acceptable reliability and validity coefficients (103). The RBANS is useful for a broad-based but intermediate level of screening for cognitive deficits in acute-care settings and for tracking improvements or declines in cognitive function over time.

### ***Goals of Neuropsychological Assessment***

The field of neuropsychological assessment has come full circle since 1935 when Halstead established his laboratory (104). Halstead observed the behavior of individuals with brain damage and then developed psychological tests to measure the characteristics that he observed. Thus, the initial goal of assessment was a better understanding of brain-behavior relationships, particularly in individuals with brain impairments. Halstead's assessment methods quickly proved their worth when used by experienced clinicians, by reliably and validly diagnosing brain damage, and localizing malfunctioning regions of the brain. Their use as a neurodiagnostic instrument gained prominence and is now routine. Their diagnostic validity has been shown to be equal to that of neurodiagnostic techniques in use before the introduction of computed tomography and magnetic resonance imaging (105). As brain imaging technology has improved, however, the importance of neuropsychological assessment has returned to the original goal of describing brain-behavior relationships.

The field of neuropsychological assessment is increasingly focusing on the development of new methods for assessing rehabilitation potential, functional competence, and valid cognitive remediation procedures for patients with brain damage (106–110). For example, Sherer et al. (111) demonstrated how early brief cognitive assessment combined with severity of head injury indicators can more reliably predict long-term employment outcome. Miller and Donders (112) demonstrated that neuropsychological assessment during acute rehabilitation significantly improved the prediction of educational outcomes in children with traumatic brain injury 2 years later. Unfortunately, most neuropsychological tests were designed with diagnosis, not prediction or remediation, as their major goal. The tests were not constructed to determine which combinations of cognitive abilities are minimally necessary for survival in complex environments. Heaton and Pendleton (113), in an early comprehensive review of the neuropsychological literature, lamented that prediction of everyday functioning is a largely ignored topic of research in a field still dominated by diagnostic issues. Optimal prediction about the satisfactory matching of persons with environments will require new approaches to the measurement of environments and careful attention to the ecological validity of neuropsychological tests (114,115).

### ***Halstead-Reitan Neuropsychological Battery***

The HRNB consists of three batteries (i.e., child, intermediate, and adult) (116). The adult version consists of Halstead's original five tests of seven variables selected for their ability to distinguish adults who have frontal lobe dysfunction. Halstead's first graduate student, Ralph Reitan, established his own laboratory and added measures of aphasia, sensory-perceptual integrity, grip strength, and sequential visual scanning, collectively entitled "Allied Procedures." In addition to the HRNB, a complete battery usually includes the WAIS-III and a measure of personality (e.g., the MMPI-2). The results of the HRNB can be presented as the Halstead Impairment Index, which is not a meaningful indicator of brain damage by itself but must be understood in the context of other test data that have been analyzed using inferential methods. Reitan described these inferential methods as follows:

*Level of performance.* The individual's score is compared with that of a criterion group and the normality of the score is determined. Statements describing the amount or degree of a specific attribute are provided.

*Pattern of performance.* Variations of scores within and between tests can be analyzed for specific strengths and weaknesses.

*Specific behavioral deficits or pathognomonic signs.* Behaviors occurring only with brain damage (e.g., anomia, hemianopsia, and hemiplegia) can be detected.

*Comparison of performance of the right and left sides of the body.* Measures of motor, sensory, and sensory-perceptual functions from one side of the body are compared with those of the opposite side. Significant discrepancies may reflect brain dysfunction and can help rule out competing explanations of poor performance on more complex neuropsychological tests.

In rehabilitation, as opposed to general medicine, the issue of diagnosing the presence of brain damage is of reduced importance. Brain damage is frequently the criterion for entry into a rehabilitation unit. Rehabilitation team members are more concerned with the degree to which the patient will be able to understand and profit from rehabilitation services or function in their home environments. As noted in the introduction to this section, a lengthy test battery may not be physically possible because of recent onset of impairment or because of shortened lengths of stay in acute rehabilitation. In these cases, the rehabilitation psychologist may administer select portions of the standard HRNB or use tests that place fewer demands on the patient such as the RBANS. A comprehensive battery of neuropsychological tests may be administered on an outpatient basis to more fully assess cognitive function and provide guidance on such issues as supervision, return to driving, and ability to return to work.

The HRNB is not without its limitations. For example, Halstead's original cutting scores were based on the performance of young patients, with age-graded norms becoming available recently (117). Patients with minimal education may spuriously score in the impaired range. Finally, the battery's ability to

consistently localize lesions and discriminate psychiatric from organically impaired patients remains problematic (118).

### ***The Boston Process Approach to Neuropsychological Assessment***

The Boston Process Approach to Neuropsychological Assessment (BPA) is the designation given to neuropsychological assessment that focuses on the manner in which the patient produced his or her response rather than concentrating solely on test norms and patterns of scores. The three goals of the BPA are to (a) understand the qualitative nature of the behavior being assessed, (b) reconcile descriptive richness with the reliability and validity of quantitative tests, and (c) relate the behavior assessed to neuropsychological theory (119).

The BPA emphasizes developmental psychology's distinction between "process and achievement" to understand cognition in individuals with brain damage. Systematic observation of the problem-solving strategies used by patients during standardized testing is the hallmark of this approach. This method allows both a quantitative assessment and a dynamic description of the information-processing style of each patient.

The BPA uses a core set of tests with supplementary tests to clarify problem areas and confirm clinical hypotheses. The core set consists of frequently used tests that assess functions in six cognitive domains including intellectual and conceptual, memory, language, visuoperceptual, academic achievement, self-control, and motor control (119). The BPA is concerned with the extent the patient gives priority to processing low-level detail or "featural" information versus higher-level "configural" or "contextual" information. Patients with impairments in contextual processing often have difficulties organizing their behavior (120).

Both the quantitative and qualitative approaches to neuropsychological assessment have proponents. The process approach is perhaps more compatible with the rehabilitation emphasis on practical and functional improvements. Given its focus on qualitative observation, the process approach provides potential insights regarding the most effective cognitive rehabilitation methods to use for remediation of cognitive deficits. Lezak et al. (118) noted that the use of fixed neuropsychological test batteries is waning in favor of a flexible choice of tests. Increasingly, the norm is for neuropsychologists to flexibly borrow from both the quantitative and qualitative traditions to design briefer batteries that are appropriate to a particular assessment question and setting (121). Moreover, the current trend toward reduced lengths of initial rehabilitation often precludes administration of a comprehensive neuropsychological test battery. A common alternative is to perform a brief assessment of cognitive function before discharge from inpatient rehabilitation followed by comprehensive assessment weeks to months after discharge. This brief initial assessment provides a "benchmarking" of current levels of cognition and can provide guidance about the amount of supervision needed for the patient. A report by the American Academy of Neurology confirmed the efficacy of neuropsychological assessment (122). Although neuropsychological assessment has proved effective

in detecting cognitive dysfunction, translating test results into ecologically valid rehabilitation recommendations has proved more elusive (123).

### **Chemical Use Assessment**

#### ***Background***

In the mid-1980s, Rohe and DePompolo highlighted the failure of rehabilitation professionals to assess and intervene in the domain of chemical health among those with disabilities. In 2002, Basford, Rohe, and DePompolo found significant improvements in chemical health screening for those with disabilities but a continued failure to provide staff training on the issue of chemical health assessment and intervention (124). Cardoso et al. (125) report continued inadequacies in the training of rehabilitation psychologists in substance abuse assessment and treatment. Throughout this section, alcohol and drug abuse are considered jointly. The focus of discussion, however, is on alcohol, the more frequently abused substance. Bombardier and Turner provide a contemporary overview of alcohol and drug use in persons with disabilities (126,127).

The importance of alcohol screening is related to both the drug's impact on bodily functions and the associated behavioral aberrations occasioned by its excessive use. Eckardt et al. reviewed the detrimental effect of alcohol on most organs, especially the liver, pancreas, and heart (128,129). Alcohol ingestion may potentiate the action of prescribed medications, most notably central nervous system (CNS) depressants. This potentiation is of particular importance for rehabilitation patients. For example, medications that control blood clot formation and reduce spasticity are frequently used with rehabilitation patients. Alcohol may decrease blood-clotting activity and act in an additive manner with muscle relaxants such as diazepam (Valium) and baclofen (Lioresal). In addition, altered consciousness may result in less vigilance in health-compromising situations. If alcohol is ingested in the form of beer, the large fluid volume could seriously compromise a bladder retraining program (130).

The cognitive and behavioral aberrations associated with drug intoxication often result in the onset of a disability. Rohe and DePompolo noted that vehicular crashes and falls, especially while the individual is under the influence of alcohol, account for a large proportion of admissions to rehabilitation units (131). Retrospective chart reviews of persons with CNS trauma often show alcohol present at the time of injury. Heinemann et al. found that 39% of their spinal cord-injured patients admitted to being intoxicated at the time of injury (132). Corrigan's review of the literature found that as many as two thirds of head-injured patients have a history of substance abuse that preceded their injury. These studies revealed alcohol intoxication present in one third to one half of hospitalizations (133). Heinemann et al. found that drinking patterns before and after SCI are strongly related (134). In a study of long-term spinal cord-injured patients, problems resulting from substance abuse were reported by more than one half of the patients sampled (135). Rivara et al. found that 47% of general trauma patients had a positive blood alcohol level and

that 36% were intoxicated (136). The preceding data suggest that individuals admitted to rehabilitation units with traumatic CNS injuries are not a random sample of the drinking public. Assessment and intervention with this population represents an opportunity at reducing future medical, social, and personal costs. Corrigan argues that rehabilitation professionals, under scrutiny from third-party payers, cannot afford to have a significant proportion of their patients display poor long-term outcomes secondary to failure to address substance abuse (133).

The screening of chemical health for all rehabilitation patients, especially those who incur their disability as a result of trauma, must become a standard of care. For this to occur, the administrators of rehabilitation facilities will have to require that drug screening be standard policy and that rehabilitation professionals, especially physiatrists, have necessary screening skills. Although one recent survey of rehabilitation unit administrators indicated that chemical health screening has become common; as recently as 1996, Schmidt and Gavin found that only 4% of persons receiving initial traumatic brain injury rehabilitation were screened for substance abuse (124,137). Thus, the data on administrators' perception of the adequacy of chemical health screening occurring in their facilities versus actual practice appear inconsistent. Unfortunately, staff training on this issue remains sorely lacking, with only 23% of rehabilitation unit administrators reporting that staff were provided education (124). Obtaining accessible substance abuse treatment for those with physical disabilities remains difficult (138). Perhaps the most overlooked chemical health issue is screening and intervention for nicotine dependence in those with disabilities. Basford, Rohe, and DePompolo point out that rates of smoking may be higher in those with disabilities when compared with the general population, and the health consequences in terms of lung function and wound healing may be particularly devastating to this population (124).

### **Screening for Chemical Dependency**

Individual attitudes about alcohol use are diverse, strongly held, and determine the perception of another person's use. Unless one first examines personally held attitudes and values about alcohol use, perceptions of another's use may be biased. A training program developed by the Center for Substance Abuse Prevention stresses the importance of attitudes in prevention programs (139). The two most frequent problems encountered during screening are viewing alcohol as a moral problem and judging the deviance of the patient's drinking through comparison with the interviewer's personal pattern of use. Weinberg stated that the most important aspects of interviewing about alcohol use are (a) getting a detailed history, (b) demonstrating nonjudgmental acceptance, (c) asking direct, specific, and factual questions, (d) maintaining persistence, (e) never discussing alibis, and (f) titrating hostility (140).

The most promising approach to helping people change their alcohol use is "motivational interviewing," which is based on Prochaska's stages of change model (141,142). Two measures useful in assessing alcohol use are the CAGE Questionnaire and the Alcohol Use Disorders Identification Test (AUDIT).

**The CAGE Questionnaire.** The CAGE Questionnaire was originally developed on 130 randomly selected medical and surgical inpatients at North Carolina Memorial Hospital. The goal was to find the least number of questions that would reliably identify those suffering from alcoholism. The four CAGE questions are

1. Have you ever felt you ought to cut down on your drinking?
2. Have people annoyed you by criticizing your drinking?
3. Have you ever felt bad or guilty about your drinking?
4. Have you ever had a drink first thing in the morning to steady your nerves or to get rid of a hangover (i.e., an eye opener)?

Ewing summarized the scale's development and data on four normative samples (143). One positive response to any of the questions raises the suspicion that alcohol dependence is present. Two positive responses identified 97% of his alcoholic sample correctly, and only 4% of his nonalcoholic sample incorrectly. Three or more responses are clearly symptomatic of alcohol dependence. The CAGE has sensitivity of from 60% to 95% and specificity ranging from 40% to 95% (144).

**The Alcohol Use Disorders Identification Test.** The AUDIT is a measure designed to aid in the process of accurate and reliable assessment of alcohol use. The AUDIT was developed by the World Health Organization to detect alcohol problems in primary medical care settings. The AUDIT consists of ten questions: three on alcohol consumption, four on alcohol-related problems, and three on alcohol dependence symptoms. The AUDIT requires 2 minutes to administer and 1 minute to score, with a recommended cutoff score of 8. Sensitivities are typically above 90%, with specificities in the 80% to 90% range (145).

In summary, the field of rehabilitation has yet to fulfill its responsibility in the screening and treatment of chemical abuse and dependency, especially nicotine dependence. Research data suggest that patients with traumatic CNS injuries have a high probability of chemical abuse. Physiatrists have a responsibility for learning the skills needed for systematic screening of their patients. This intervention, early in the rehabilitation process, is a crucial aspect of prevention of future medical complications. For example, Bombardier et al. have studied both those with recent SCI and Traumatic Brain Injury (TBI) in the inpatient setting. For both patient groups they found that the majority of at-risk drinkers were considering changes in their alcohol use. They conclude that intervening shortly after the onset of disability provides a window of opportunity to reduce post-injury alcohol abuse and related impairments (146,147).

## **Psychotherapeutic Interventions**

### **Individual Psychotherapy**

*Psychotherapy* is a generic term denoting psychological interventions that ameliorate emotional and behavioral difficulties. Psychotherapy can be defined as an interpersonal process whose goal is modification of problematic affect, behavior, or cognition (148). Although there are more than 130 varieties of psychotherapy, psychotherapy research has become

increasingly sophisticated in understanding key variables (149). Current research is focused on what specific types of therapy are best suited for what particular patient groups. For example, meta-analytic studies indicate that cognitive-behavioral therapy is as effective as anti-depressant medication for individuals with MDD. The effectiveness of psychotherapy seems to be related to a therapist's degree of training in, and enthusiasm for, the theory and methods espoused by the particular therapy. Data suggest that psychotherapy does produce measurable change in patients. This change, however, can be negative as well as positive. The important principle of "above all, do no harm" is as important in psychotherapy as it is in medicine. Inadequately trained therapists are thus a source of concern in a field lacking firm boundaries.

The three basic assumptions underlying psychotherapy are as follows:

1. The person seeking services desires change.
2. The dysfunctional affect, behavior, or cognition is understood and amenable to change.
3. The process is a collaborative endeavor that assumes active client participation.

Psychotherapeutic intervention is thus contraindicated in patients on whom it must be forced or in those with significant communication or learning impediments. Additionally, if the difficulties are due to factors solely in the patient's environment (e.g., long hospitalization, unpleasant medical interventions, prejudice, non-understanding staff), the focus of the psychotherapist's intervention may shift from the patient to the environment (150).

The qualities of effective therapists have been studied and delineated. Therapeutic effectiveness initially depends on good assessment skills. Knowing when and how to intervene and, conversely, when to do nothing is fundamental to the process. Effective therapists are able to instill trust, confidence, and hope in their clients. Regardless of the type of therapy practiced, effective therapists have been shown to communicate the specific attitudinal qualities of genuineness, unconditional positive regard, and empathy. As opposed to mere friendship, the therapist provides an atmosphere of acceptance, respect, understanding, warmth, and help in conjunction with deliberate efforts to avoid criticizing, judging, or reacting emotionally with the patient. The creation of this atmosphere results in a framework unmatched by any other human relationship, one conducive to therapeutic change.

Most patients in rehabilitation units are faced with discovering and coping with permanent physical, cognitive, and social losses. This discovery is frequently accompanied by anger, anxiety, dysphoria, grief, and fear. Clinical experience suggests that the patient population can be divided into thirds according to the severity of their reactions. One third of the patients copes extremely well through use of previously established skills and the support of significant others. Another one third has greater difficulties, but with brief psychotherapeutic intervention is able to successfully manage the crisis. The final one third has significant difficulties in

coping. These patients frequently have histories of difficulties in adjustment, such as chemical abuse, major mental disorder, and inability to tolerate structured living environments. This group is of paramount concern to the rehabilitation psychologist and consumes disproportionate amounts of professional time.

Because of the pressing practical problems faced by rehabilitation inpatients and the increasingly short periods of hospitalization, rehabilitation psychologists tend to use time-limited forms of therapy, also known as brief therapy. Brief therapy is a general term denoting therapies with a small number of sessions (i.e., six to ten) and limited, focused, and readily attainable goals. These goals often include amelioration of the most disabling symptoms, reestablishment of previous levels of functioning, and development of enhanced coping skills. The sessions are focused on concrete content and the "here and now." Rehabilitation psychologists frequently apply techniques termed *cognitive-behavioral*. This concept is described by Turk et al. (151).

There are several common elements of cognitive-behavioral therapy. Interventions are active, time-limited, and fairly structured, with the underlying assumption that affect and behavior are largely determined by the way in which the individual construes the world. Therapy is designed to help the patient identify, reality-test, and correct maladaptive, distorted conceptualizations and dysfunctional beliefs. The patient is assisted in recognizing the connections among cognition, affect, and behavior, together with their joint consequences and is encouraged to become aware and monitor the role that negative thoughts and images play in the maintenance of maladaptive behavior.

### Behavioral Management and Operant Conditioning Techniques

In contrast to many specialty areas of medicine, in rehabilitation medicine there is a strong and systematic interaction between the medical and the behavioral sciences. Because of their relevance to rehabilitation, the principles underlying behavior modification are discussed in detail. Included are the topics of token economies, behavioral contracting, and misconceptions about behavior modification. The following material is drawn from the writings of Martin and Pear (152), Reynolds (153), Kazdin (154), and Brockway and Fordyce (155).

#### Types of Reinforcers

There are three types of reinforcers. *Primary* or *unconditioned reinforcers* are present at birth. They include food, water, sexual stimulation, rest after activity and activity after rest, a band of temperatures, air, and cessation of aversive stimuli. *Conditioned reinforcers* are stimuli that have been repeatedly paired with primary reinforcers. They are idiosyncratic and are based on the learning history of the person. *Generalized reinforcers* are stimuli that have been paired with two or more conditioned reinforcers. The prime example of a generalized reinforcer is money; however, verbal responses such as "thank you," "correct," and "great" also are in this category. In addition to

the three types of reinforcers, there is an important principle, the Premack principle, which states that any high-frequency behavior can be used to reinforce a low-frequency behavior. For example, a high-frequency behavior such as watching television can be made contingent on performing a low-frequency behavior such as stretching exercises.

### ***Token Economies***

A token economy refers to a reinforcement system based on tokens. The tokens, frequently poker chips, function as generalized reinforcers and can be exchanged at agreed-on rates for back-up reinforcers, such as food, activities, and privileges. The behaviors to be changed (i.e., target behaviors) are specified along with the number of tokens earned for their performance. The stipulations of the economy are usually written in the form of a contract, a “reinforcement menu,” that indicates exchange rates and back-up reinforcers and is displayed in a prominent place. Token economies have been used extensively in special education and psychiatric settings. They can be useful with troublesome rehabilitation patients for such behaviors as arriving at therapy sessions late, lack of compliance with fluid schedules, and failure to perform activities of daily living. As with behavioral contracts, ethical considerations and the success of the program mandate full involvement of the patient in the initial design of the program.

### ***Behavioral Contracts***

Behavioral contracts, also known as contingency contracts, are written agreements between people who desire a change in behavior. The contract precisely indicates the relationship between behaviors and their consequences. The contract serves four important functions. First, it ensures that the rehabilitation team and the patient agree on goals and procedures. Second, because the goals are specified behaviorally, evidence is readily available regarding fulfillment of the contract. Third, the patient has a clear picture of what behaviors are expected if he or she is to remain in the rehabilitation program. Fourth, the signing of a document functions as a powerful indicator of commitment and helps ensure compliance with the agreement.

### ***Common Misconceptions about Behavior Modifications***

Behavior modification arouses concerns usually because of a misunderstanding of its underlying principles. Kazdin presented a succinct overview of common objections, two of which are iterated here (154). A frequent objection is that use of tangible reinforcers is the same as bribery. Bribery can be differentiated from reinforcement, because bribery is used to increase behavior that is considered illegal or immoral and usually involves delivery of the payoff before performance of the behavior, not, as in behavior modification, after. Bribery and reinforcement share the similarity of being ways of influencing behavior, but that is where the similarity ends.

A second objection is that behavior modification is “coercive.” Although behavior modification is inherently controlling

and designed to alter behavior, multiple safeguards prevent its misapplication. These safeguards include involving the patient when contingencies are negotiated, constructing programs that rely on positive reinforcement rather than negative reinforcement or punishment, and making response requirements for reinforcement lenient at the beginning of the program (156). The use of behavioral modification in rehabilitation units requires careful training of staff. A limiting factor in many inpatient rehabilitation units is the lack of stability in team membership, especially where nursing personnel change frequently.

### ***Social Skills Training***

#### ***Changes in Social Interaction after Disability***

Although only a limited number of the recently disabled may profit from psychotherapy, based on the author’s clinical experience many can benefit from social skills training. Research on the social psychology of disability is plentiful and underscores the social disadvantages encountered by the disabled, especially the recently disabled (157–169). Richardson summarized the literature and found consistently negative public attitudes toward the disabled (166). He noted that when first encountering a disabled person, the nondisabled experience heightened emotional arousal, anxiety, and feelings of ambivalence. These learned but somewhat involuntary reactions usually result in distorted social interactions.

Often the nondisabled focus solely on the disability and ignore personal characteristics normally used to evaluate people and establish relationships. The disabled also suffer from the societal norm to be kind to the disabled, which results in a lack of honest feedback and concomitant decreased accuracy in social perception by the disabled person (170). Consequently, the physically disabled often learn to discount praise and pay close attention to criticism. The factors mentioned earlier suggest that social interactions between the disabled and the nondisabled are complex, ambiguous, and unpredictable. Interventions that ameliorate difficulties with social interaction might help reduce emotional distress, speed the slow process of community reintegration, and reduce the risk of future medical problems (171).

#### ***Social Skills: Types and Methods of Assessment***

*Social skills* is an inexact term used to describe a wide range of behavior thought necessary for effective social functioning. Dunn and Herman listed three types of social skills: general, general disability-related, and specific disability-related (Table 14-7) (172). Patients with the onset of disability before adolescence may require intensive remedial help with the development of general social skills. Patients with the onset of disability after adolescence enter the social arena with various competencies in general social skills. However, those with the onset after adolescence experience social situations for which they have no previous socialization experiences, hence the importance for training to handle these situations. General social skills can be assessed through a variety of means, including paper and pencil tests, behavioral assessment, and observational techniques.

**TABLE 14.7** General, General Disability, and Disability-Specific Social Skills

General Social Skills
Listening
Positive and negative assertion
Self-disclosure
Receiving compliments
Confrontation
Touching
Conversation
Maximizing physical attractiveness
Meeting new people
Use of humor
Heterosocial skills
General Disability-Related Social Skills
Acknowledgment of the disability
Asking for help
Acknowledgment of unstated attitudes (making the implicit explicit)
Refusing undesired help
Managing unwelcome social advances
Dealing with staring
Handling unwanted questions
Disability-Specific Social Skills
Facilitating communication
Overcoming early deficits in socialization
Managing bowel and bladder problems
Handling reactions to deformity and disfigurement
Disclosing nonvisible disabilities
Dealing with reactions to prostheses

From Dunn ME. Social skills and rehabilitation. In: Caplan B, ed. *Rehabilitation Psychology Desk Reference*. Rockville, MD: Aspen Publishers; 1987:345–381, with permission of the publisher.

A social skill frequently identified as a problem is assertiveness; hence, it is used here to illustrate three assessment methods. A paper-and-pencil measure of assertiveness is the Gambrell Assertion Inventory (GAI) (173). The GAI presents 40 situations described by a short phrase—for example, “turn off a talkative friend.” The subject then rates his or her degree of discomfort for each situation on a five-point scale ranging from “none” to “very much.” Next, the subject rates his or her response probability for each situation on a five-point scale ranging from “always do it” to “never do it.” Normative data allow comparisons with the general population and with those having assertiveness difficulties. A measure of assertiveness more relevant to disability is the SCI Assertion Questionnaire (174). The format of this questionnaire is similar to that of the GAI, but social situations that are potential problems for wheelchair users are described.

Behavioral measures help clarify the frequently found discrepancy between what people say they do and what they actually do. Behavioral measures offer direct and quantifiable data on both verbal and nonverbal aspects of social interactions. Such measures might include checklists or rating

scales that permit counting responses, measuring length of time spent interacting, and so on. For example, studies using behavioral measures have shown that disabled people receive offers of help from strangers less frequently than do the non-disabled. However, if help is offered to the disabled, it tends to be overly solicitous (175,176). Hastorf et al. (170) found that strangers were more willing to work on a cooperative project if the disabled partner assertively acknowledged the handicap at the beginning of the interaction. Finally, behavioral measures have been used during evaluation of the efficacy of assertion training with disabled people (177–180).

Observational techniques can be used by the person, significant others, or staff members. Generally, this type of assessment is less objective than that provided by behavioral measures. Nonetheless, reduced precision is counterbalanced by the opportunity to observe qualitative aspects of the social skill in a natural setting. Several research projects (e.g., Longitudinal Functional Assessment System and Rehabilitation Indicators Project) use observational techniques in the form of diaries, self-reports, and environmental surveys. Thorough descriptions of methods of assessing social skills can be found in a variety of publications (177,181,182). The reader is encouraged to consult relevant social skills training manuals for intervention techniques (183,184). Social skills training programs for wheelchair users are described by Dunn and Herman (172). Brotherton et al. (185) describe a program for the traumatic brain injured.

## INDIRECT SERVICES

The rehabilitation psychologist’s overall aim is to enhance the quality of rehabilitation outcomes for patients. Indirect services such as maximizing team interaction skills, staff development, administration, and research provide avenues for enhancing patient outcomes that are as important as those of direct patient services.

The rehabilitation team is a unique structure in the delivery of health-care resources (186). Nowhere else are so many professionals with diverse backgrounds of training expected to communicate in a clear, timely, and comprehensive manner. This communication may become tenuous because of different professional terminologies, overlap in roles, and the pressures of productivity in a competitive health-care environment (187). The psychologist can enhance patient outcomes by facilitating cohesion of the rehabilitation team (188). This task can be accomplished through a variety of methods, including chairing committees to improve interdisciplinary cooperation and leading staff meetings to clarify overlap in professional roles. Butt and Caplan provide a comprehensive review of the rehabilitation psychologist’s role in the rehabilitation team (189). In the author’s experience, rehabilitation psychologists play a variety of roles in relationship to the rehabilitation team. The rehabilitation psychologist’s knowledge of distinguishing normal from abnormal behavior in adjustment to trauma and disability is frequently utilized for staff education. Although some

in-service topics focus on patient variables, such as practical management suggestions and brain-behavior relationships, other topics include personal concerns of the staff such as job stress and communication skills. The psychologist's strengths in interpersonal communication frequently prompt their selection for administrative positions.

Rehabilitation psychologists trained at the doctoral level typically have extensive expertise in research design and statistical methods. As such, they frequently consult with other team members interested in conducting research. They may coordinate research or direct research committees. The research expertise of psychologists is reflected in their presence on editorial boards of numerous rehabilitation-related publications. They are also found in local, state, and national organizations whose function is to promote quality rehabilitation and social justice for the physically disabled.

## PSYCHOLOGICAL ADJUSTMENT TO DISABILITY

This section is divided into two parts. The first part reviews theories of adjustment to disability. The second part describes three models of adjustment to disability. The stage model emphasizes internal cognitions; the behavioral model emphasizes external events; and the coping skills model emphasizes both internal cognition and external events in the adjustment to disability.

### Overview of Theories of Adjustment to Disability

Theories of adjustment to disability can be grouped along an internal to external continuum (190). On one end are theories that emphasize internal cognitive events, termed *mentalist theories*, and on the other end are theories that emphasize events external to the individual, termed *social theories* or *behavioral theories*. The middle of the continuum contains integrative theories that attempt to meld the internal with the external determinants.

Before formal theorizing about adjustment to disability, most people thought that the primary source of suffering connected with disability was the disability itself. Hence, removal or amelioration of the disability would presumably reduce distress. However, experience demonstrated that after removal of a disability, some people remained incapacitated. The search for understanding the adjustment process shifted to the then contemporary principles of dynamic psychology and focused on internal events such as motivation. Patients' difficulties in adjusting to disability were conceptualized in psychodynamic terms, and their incapacitation was transformed into a mental health problem.

As time progressed, dynamic psychology models, especially the classic psychoanalytic model with its emphasis on psychopathology, provided insufficient explanatory power. Professionals came to recognize that physical and social barriers, barriers external to the patient, produce the major source of adjustment problems. Emphasis on sociologic concepts such as "sick role" (191) and "illness behavior" (192) ensued. These

sociologic theories added to the understanding of adjustment to disability on a societal level (193). When an individual's adjustment to disability behavior is the focus, however, learning theory's emphasis on the sensitivity of behavior to its consequences provides significant explanatory power. The behavioral model of adjustment to disability is described more fully in a later section.

Theories that attempt to simultaneously take into account the internal events of the person and the external demands of the environment are called *integrative field theories* (190,194,195). Integrative field theories grew out of Lewin's concept of life space (196). These theories state that behavior is a joint function of the person and his environment [ $B = f(P, E)$ ]. Meyerson, Trieschmann, and Wright applied Lewin's basic formulation to problems encountered by the physically disabled (164,197,198). For example, Trieschmann expanded Lewin's model and described the "educational model of rehabilitation" in which behavior is the function of personal, organic, and environmental variables, designated by the formula  $B = f(P \times O \times E)$ . Her acknowledgment of organic variables highlights the concept that behavior is fundamentally dependent on and limited by the physical capacities of the person.

### Models of Adjustment to Disability Stage Model

Stage theory states that people undergoing a life crisis follow a predictable, orderly path of emotional response. Shontz is the major contributor to the application of stage theory to adjustment to disability (199). Stage theory appears both explicitly and implicitly in a wide variety of rehabilitation-related literature, including that on cancer, hemodialysis (200,201), SCI (202–204), and amputation (205). Additional writers who make implicit or explicit reference to a stage model of adjustment to disability are Dembo et al., Siller, and Guenther (159,167,206). Unfortunately, these studies are merely descriptive and are based on interview data or anecdotal reports.

Most stage theories propose a series of three to five steps beginning with shock and ending with some form of adaptation. Three commonly held assumptions appear to underlie stage theory formulations applied to the disabled. First, people respond to the onset of disability in specific and predictable ways. Second, they go through a series of stages over time. Finally, they eventually accept or resolve their emotional crises. The following discussion draws on the work of Silver and Wortman (207–209) and Trieschmann (197). Much of the stage theory literature is derived from the study of bereavement. Although there are important differences between the death of a significant other and loss (death) of a body part or function, it is reasonable to assume that the processes of coping with death and coping with disability are psychologically similar if not equivalent.

### Are There Universal Responses to Disability Onset?

Both Guenther (206) and Shontz (199) indicated that once the crisis of disability is realized, virtually all people experience shock. Unfortunately, most studies report retrospective accounts of initial feelings and behavior. In one such study,

Parkes interviewed widows and amputees after their losses (205). Initial feelings of shock and numbness were reported by only 50% of the sample. Tyhurst observed disaster victims and described three types of reactions (210). One group reacted with classic signs of shock, another group appeared cool and collected during the acute situation, and a third group responded with reactions of paralyzing anxiety and hysterical crying. Shock was far from a universal reaction. Silver and Wortman's 1980 literature review concluded that there is little evidence supporting the belief that people react in specific and predictable ways to undesirable life events (207). Although some patterns are evident, individual variation is inevitably present. Their updated (2001) literature review found no research that would compel them to revise their earlier conclusion. The author's clinical experience supports this conclusion. The initial reaction to the onset of disability is diverse. Moreover, the more accurate the first thought after the onset of disability (termed by the author the *sign-on cognition*) and the more honest the self-acknowledgment, the better the initial and longer-term adjustment appears to be. Further research on the concept of sign-on cognition may prove useful in understanding the process of adjustment to disability.

### Do Emotional Responses Follow a Pattern After Injury?

The belief that people follow a predictable pattern of emotional response after the onset of a disability is widely held. References to stage models of emotional response occur in the professional literature of nurses (211,212), social workers (213), clergy (214), health-care professionals (215), and psychologists (167,199,206).

Silver and Wortman were unable to discover any studies specifically testing stage theory by measurement of affective states over time (207,209). Four related studies, all conducted on patients with SCI, failed to support stage theory. Dunn, cited by Trieschmann studied seven psychological variables during three time periods of inpatient rehabilitation (197). He found no pattern of change in mood over time; variability was the norm. McDaniel and Sexton assessed psychological status over four points in time from ratings by rehabilitation team members (213). Ratings of negative mood states remained relatively constant over the length of the study and were independent of staff ratings of the patient's degree of acceptance of loss. Dinardo, in a cross-sectional study, found that the degree of depression experienced by his subjects was independent of the time that had elapsed since their injury (216). Finally, Lawson, in a longitudinal study, used a variety of methods to assess the presence of depression (217). He found no period of at least a week when any of his patients scored consistently in the depressive range on any of the measures. His results suggest that patients with SCI do not experience a stage of depression during initial rehabilitation.

Although there is considerable popular and professional literature attesting to the veracity of stages of adjustment to disability, the empirical data do not support such a contention. Silver and Wortman summarized the available data by

stating, "Perhaps the most striking feature of available research, considered as a whole, is the variability in the nature and sequence of people's emotional reactions and coping mechanisms as they attempt to resolve their crises" (207). Their follow-up review of the literature highlighted that there are deep-seated assumptions about how people "should" react to loss. These assumptions include that (a) individuals suffering a loss are supposed to go through a period of intense distress; (b) failure to experience intense distress is suggestive of a problem; (c) successful adjustment requires that the individual "work through" his or her feelings; (d) continued attachment to the deceased (in the case of disability, attachment to previous levels of body function) is viewed as pathologic; and (e) within a year or two people will recover from their loss and return to earlier levels of functioning (209). They note that individuals who do not comply with these assumptions may incur negative reactions from their peers and subsequently shift their behavior to be in accord with others' expectations.

### Is a Final Stage of Resolution Reached?

Do people who have suffered a major undesirable life event eventually reach a final stage of resolution or acceptance of their disability? The findings across studies suggest that a large minority of people continue to suffer years after a traumatic life event. The unquestioned expectation of resolution or acceptance appears unwarranted for such traumatic life events as severe burns, SCI, cancer, death of a spouse, and rape (207,218). For example, Shadish et al. studied a cross-sectional sample of patients with SCI (219). They found that those who had been disabled for as long as 38 years continued to think about and miss physically impossible activities.

Wortman et al. discuss a theoretical framework that suggests that the impact of a major undesirable life event is determined by whether the event can be incorporated into an individual's view of the world (220). The term *world-view* denotes the system of beliefs, assumptions, or expectations related to oneself, others, and the world that provides a sense of coherence and meaning (221). Losses that are sudden, uncontrollable, and random may readily shatter people's assumptions about the world. Thus, the extent to which an individual's worldview is violated will determine the intensity of the disequilibrium and distress that they experience. The degree to which they can reconcile the event with their pre-existing worldview or create a new worldview that adequately accounts for the event will determine their long-term adjustment. Hence, disability of sudden onset would have a greater impact on worldview than disability caused by chronic illness.

Given the lack of support for three common assumptions underlying stage theory, one must consider alternative explanations of why such beliefs permeate clinical folklore and descriptive writing in the area. As suggested earlier, stage theory may represent a codification of strongly but implicitly held culturally determined expectations about reaction to loss. Two additional reasons come to mind. First, professionals working with the recently disabled often encounter unpredictable and emotionally charged situations. One way to help neutralize

fears occasioned by such situations is to label the patient as being in a particular stage. This may help transform potentially threatening and seemingly unpredictable behavior into meaningful and predictable categories. A negative outcome of such conceptualizing may be the documented tendency for rehabilitation personnel to overdiagnose psychopathologic conditions in patients (222). This interpretation of behavior may also result in the staff inappropriately distancing themselves from the patient by negating the necessity for careful listening. A second reason may be the enticing belief that all patients eventually resolve the negative effect occasioned by their disability and achieve a final stage of adjustment or resolution. Such a belief has intrinsic appeal to health-care professionals who strive to maximize functional abilities and enhance quality of life.

### Behavioral Model

The behavioral model of disability adjustment emphasizes the importance of external factors in determining a person's adjustment. In this model there is reduced interest in the patient's cognitions and a primary focus on observable behaviors. The most frequently cited proponent of this model is Fordyce, and much of what follows is culled from his writings (155,223). Additional applications of the behavioral model to rehabilitation problems can be found in the works of Ince (224) and Berni and Fordyce (225). In the behavioral model of adjustment to disability, the newly disabled face four tasks. The patient must remain in the rehabilitation environment, eliminate disability-incongruent behaviors, acquire disability-congruent behaviors, and maintain the output of disability-congruent behaviors.

The onset of physical disability and entry into the rehabilitation environment represent punishment. In learning theory, punishment is defined as the loss of access to positive reinforcers or the response-contingent onset of aversive stimuli. Thus, the newly disabled find themselves initially operating under a pattern of punishment. Two types of behavior follow the onset of aversive stimuli. The first is escape or avoidance, and the second is aggression. Escape or avoidance behavior is frequently seen in the rehabilitation setting in the form of daydreaming, verbal disclaimers of disability, unauthorized forays off the medical unit, and refusal to participate in scheduled treatments. Aggressive behaviors may consist of either rebellious behavior or verbal and sometimes physical attack. If avoidant or aggressive behaviors are not understood and dealt with therapeutically, rehabilitation may end prematurely.

The intervention strategy for these problems involves the discovery and, if possible, reduction of aversive aspects of the rehabilitation environment. This is accompanied by reinforcement of approximations to active participation in the rehabilitation program. Selecting and systematically graphing a mutually agreed indicator of rehabilitation progress can help the patient focus on tangible improvements. Patient reactions of hostility are common and should be tolerated within limits. These reactions should never be dealt with through counter-hostility, which only increases the probability that the environment, including the treatment staff, will

become conditioned aversive stimuli. Systematically ignoring unwanted behavior and establishing therapeutic rapport enhance the probability that the patient will remain in the rehabilitation environment.

The reduction of disability-inappropriate behaviors and the acquisition of disability-congruent behaviors are synonymous with the concept of "adjustment to disability." Disability-inappropriate behaviors are decreased by withdrawal of reinforcers after their occurrence, a process known as extinction. Paradoxically, the laws of behavior demonstrate that withdrawal of reinforcers initially results in a temporary increase in the rate of behavior. This is true for both verbal and performance behaviors.

The patient's verbal behavior is likely to change more slowly than performance behavior. Statements indicating a belief in the eventual return of physical function may require years to extinguish. The staff should neither reinforce nor punish unrealistic verbalizations. Rather, a verbal response suggesting the need to maintain hope tempered with a focus on the present is least likely to offend the patient. These statements of patients are more frequent at the onset of rehabilitation and may reflect the beginning of extinction. Detailed explanations of anticipated recovery of functional abilities help decrease unrealistic patient or family verbalizations and keep everyone focused on achievable functional goals. This is especially important for family members, who may erroneously believe that the proper way to help the disabled family member cope is through agreeing with unrealistic fantasies about eventual recovery of function.

Difficulties in the acquisition of disability-congruent behaviors are usually considered to be problems in motivation. Learning theory rejects this formulation because it relies on an inference about the internal state of the person. Usually, this label is applied to people who have failed to reach expected levels of performance set by the rehabilitation staff. In learning theory, the problem is that of adjusting contingencies to increase the rate of desired behavior or reduce the rate of behaviors competing with the desired behavior. Unfortunately, most disability-congruent behaviors are initially of low frequency, strength, and value. The steps in changing this situation include establishing reinforcing relationships with the treatment staff, enhancing long-term reinforcers for disability-congruent behaviors, and introducing contingency management interventions that promote the acquisition of disability-congruent behaviors.

Maintaining the output of disability-appropriate behaviors is the final and most important step in adjustment to disability. Rehabilitation is unsuccessful if the behaviors learned in the rehabilitation unit cannot be transferred to the patient's home environment (226). Although the patient may demonstrate the ability to perform a task, the probability of its occurrence depends on contingencies operating in the home environment. Disability-congruent behaviors, such as propelling a wheelchair, maintaining a fluid schedule, and using gait aids are unlikely to be reinforcing in themselves.

Two strategies for improving generalization are bringing disability-congruent behaviors under the control of reinforcers occurring naturally in the environment and reprogramming the patient's home environment to deliver appropriate reinforcement contingently. The first strategy is promoted through interventions designed to reengage the patient in meaningful vocational and avocational activities after dismissal. Therefore, vocational counseling and therapeutic recreation are important as part of inpatient rehabilitation. Gradual and systematic rehearsal of newly learned skills in the home environment during week-end visits is an additional method encouraging generalization. The second strategy is promoted through such interventions as home modifications, assigning a family member to monitor and reinforce home therapy programs, and contracting with the patient for continued compliance. Unfortunately, powerful contingencies may be operating to prevent generalization. For example, the patient may receive reinforcers in the form of increased attention or financial rewards from litigation, a condition also known as secondary gain. Inability to control sources of secondary gain may prevent generalization of disability-congruent behaviors to the home environment. Family interventions are critical to prevent these problems.

### **Coping Skills Model**

The coping skills model (227), which emphasizes both cognitive and behavioral factors, is based on the crisis theory originally formulated by Lindemann (228). Crisis theory asserts that people require a sense of social and psychological equilibrium. After a traumatic event, a state of crisis and disorganization occurs. At the time of the crisis, a person's characteristic patterns of behavior are ineffectual in establishing equilibrium. This state of disequilibrium is always temporary, and a new balance is achieved within days to weeks. Veninga provides a practical guide for negotiating the dilemma of a crisis (229). Snyder's edited text on coping research is a must read for those interested in understanding both the theoretical constructs and the practical steps that underlie successful adaptation to loss and change (230). Snyder's seminal contributions to "hope theory" are closely linked with the coping skills model (231). Moos' coping skills model comprises seven major adaptive tasks and seven major coping skills. The coping skills are elaborated in the following discussion.

### **Denying or Minimizing the Seriousness of a Crisis**

This coping skill may be directed at the illness or at its significance and helps to reduce negative emotions to manageable levels. This reduction enhances the mental clarity needed for effective action in emergency situations. The likelihood of implementing a greater range of coping responses is also increased.

### **Seeking Relevant Information**

Often, misunderstanding of medical diagnoses and procedures causes emotional distress. Understanding often reduces anxiety and provides a sense of control. Gathering information gives the patient and family a concrete task and the accompanying feeling of purposefulness. One longitudinal study of people

with chronic illness showed that information-seeking has salubrious effects on adjustment (232).

### **Requesting Reassurance and Emotional Support**

The literature shows that perceived social support, adjustment during a crisis, and improved health outcomes are interrelated (233–235). Component parts of social support include perceiving that one is cared for, being encouraged to openly express beliefs and feelings, and being provided material aid. Social support may enhance coping by reducing counterproductive emotional states, building self-esteem, and increasing receptivity to new information. Cobb suggested that social support enhances health outcome either directly through neuroendocrine pathways or indirectly through increased patient compliance (236). He cited evidence showing that patients who receive social support are more likely to stay in treatment and follow their physicians' recommendations. Turner found a reliable association between social support and psychological well-being, especially during stressful circumstances (237).

### **Learning Specific Illness-related Procedures**

Learning specific illness-related procedures is a skill that reaffirms personal competence and enhances self-esteem, which is often undermined by physical disability. Bulman and Wortman asked social workers and nurses on a rehabilitation unit to define good and poor coping in patients with SCI (238). Both groups agreed that good coping included the willingness to learn physical skills that would minimize disability. Conversely, the definition of poor coping included an unwillingness to improve the condition or attend physical therapy.

### **Setting Concrete Limited Goals**

Limited goal setting breaks a large task into small and more readily mastered components. As each component is mastered, self-reinforcement accrues and sets the stage for further learning. Limited goal-setting decreases feelings of being overwhelmed and enhances the opportunity to achieve something considered meaningful.

### **Rehearsing Alternative Outcomes**

Activities such as mental rehearsal, anticipation, discussions with significant others, and incorporation of medical information are involved in this skill. Here the patient considers possible outcomes and determines the most fruitful manner of handling each. Recalling previous periods of stress and how these were successfully managed is an example of this coping skill. The patient engages in behaviors that alleviate feelings of anxiety, tension, fear, and uncertainty. A cognitive road map is delineated to provide guidance on how any of a variety of possible future stressors will be minimized.

### **Finding a General Purpose or Pattern of Meaning in the Course of Events**

Physical disability is a crisis that can destroy a person's belief that the world is a predictable, meaningful, and understandable place. There appears to be a compelling psychological need to

believe that the world is just (239) and to make sense out of a crisis experience. The previously discussed concept of worldview, with its focus on coherence and meaning, is relevant in this context. Some theorists claim that the search for meaning is a basic human motivation (240). Bulman and Wortman studied 29 subjects with SCI and concluded that the “ability to perceive an orderly relationship between one’s behaviors and one’s outcomes is important for effective coping” (238). Krause, in a 15-year prospective study of persons with SCI, found that survival was directly related to higher activity levels and being employed (241).

## SUMMARY

This chapter reviewed the history and current status of rehabilitation psychology, followed by an overview of services offered by the rehabilitation psychologist and theories of adjustment to disability. Although the rehabilitation psychologist provides a wide variety of direct and indirect services, certain skills are particularly relevant to rehabilitation, including psychological assessment, behavior modification, and research. Rehabilitation environments represent settings in which people under physical and emotional distress are asked to learn. Many of these people not only are emotionally upset but may have brain injuries that further impair learning efficiency. Standardized measurement of personality, mood, intellectual ability, academic achievement, neuropsychological integrity, and chemical health provide a reliable base on which to set rehabilitation goals.

Rehabilitation is concerned with the functional performance of a person. Rehabilitation team members provide diverse interventions to ensure that the person can physically perform specific activities. Whether this person will actually do so is determined by contingencies in the rehabilitation unit and home environment. The rehabilitation psychologist’s behavioral modification skills permit the careful assessment and harnessing of these contingencies in the service of the patient.

Progress in any scientific field depends on quality research. Such research is of particular concern for rehabilitation because outcomes are determined by a complex set of physical and social variables. Doctoral-level psychologists are typically the only rehabilitation team members with training in research. Traditionally, this training stresses asking practical research questions relevant to clinical problems.

Theories of adjustment to disability can be grouped along a continuum stressing internal cognitive events on the one end and external social and behavioral events on the other. Stage theory is a widely held but largely unsubstantiated model that stresses internal events. Alternative models worth considering include the behavioral model and the coping skills model. Contemporary research on the concepts of coping and hope provide a compelling theoretical basis for understanding the process of adjustment to disability and chronic illness.

# Speech, Language, Swallowing, and Auditory Rehabilitation

## INTRODUCTION

Human communication involves the exchange of information and ideas through various processes commonly referred to as speech, language, cognition, and hearing. It is thought that the study of speech communication is one of the oldest academic disciplines with roots dating back to the time of Aristotle. Despite technological advancements, human communication has retained its value because of its practical nature in the transfer of meaningful information amongst individuals. The components of human communication are dynamic and multidimensional, which are continuously influenced by physiological, psychological, and environmental factors. Human communication occurs through a series of autonomic processes mediated by the central neurological system and monitored via a sensory feedback loop. Although complex, the components of communication can be simplified into a four-step process:

- Encoding: the speaker creates the message in his or her mind
- Transmittal: the speaker sends the message
- Reception: the listener receives the message
- Decoding: the listener breaks down the message in his or her mind

This chapter serves to improve the understanding of human communication by describing the processes of speech, language, cognition, and hearing. Additionally, oropharyngeal swallowing is reviewed due to its anatomical and physiological similarities to speech production. Descriptions of commonly recognized acquired disorders in the adult population are reviewed to facilitate understanding of the rehabilitative assessments and management.

## COMMUNICATION

Human communication is often described as a well-coordinated, timed, multidimensional group of processes used to share thoughts, ideas, and emotions. The processes include speech, language, cognition, and hearing. Speech is the system that produces individual sounds, which, when placed together, develop meaningful messages. It is the verbal means of communication often thought of as the motor vehicle for message delivery. Language may be defined as an arbitrary system of

signs or symbols used according to prescribed rules to convey meaning within a linguistic community (1). Language forms the set of rules shared by communicators consisting of morphology, syntax, semantics, and pragmatics. Cognition refers to the mental processes by which one recognizes, manipulates, and exchanges information to better “understand and make sense of the world” (<http://www>, December, 2008). Cognition gives rise to the thoughts and ideas for which one uses speech and language. Hearing is the ability to detect and assign meaning to sounds. In the case of speech, hearing serves as the system that closes the communication loop.

## COMMUNICATION PATHOLOGY

A pathologic condition that affects any one of the organs involved in the process of speech or language influences the total final product. Frequently, the pathologic condition often is limited to a single speech or language component, and the dysfunction can be detected in only one specific parameter such as an isolated voice or articulation impairment. More commonly, however, the pathologic condition of a single organ influences other elements of the communication process in ways that are predictable when one considers the integrated nature of speech and language. For example, severe obstructive pulmonary disease does not just impair the respiratory support for speech but results in alterations in vocal pitch, vocal intensity, and phrasing or prosody, as the speaker compensates for an impaired ability to sustain airflow. Certain disease states, involving organs that are not directly involved in speech or language, can affect the final vocal product in a secondary manner. For example, some endocrine disorders, such as hypothyroidism, can influence voice quality as an isolated component of speech. It can also lead to language confusion and impaired memory. Because of the complexity and interactive nature of the speech and language processes, whenever one evaluates or treats a patient with a communication disorder, some considerations must be given to overall human physiology, as well as to the dynamics of speech and language systems. Many professionals including audiologists, physiatrists, and otolaryngologists contribute to the assessment and treatment of communication. Speech-language pathologists have the specialty training in the communication impairments and are

credentialed to assess, treat, and manage the communication disorders with the ultimate goal of developing and maintaining a functional communicative status for individuals.

## SPEECH PRODUCTION

Speech production requires multiple physiological systems working together to create an intelligible message. The five systems comprising speech production include respiration, phonation, resonance, articulation, and hearing. Although each system works concurrently with each other to achieve the end result of speech, it is often easier to understand the complexity of the systems by reviewing them as separate entities.

### Respiration

Two forms of respiration are recognized: chemical and mechanical. Chemical respiration is concerned with the exchange of oxygen and carbon dioxide to and from the blood, whereas mechanical respiration (or ventilation) is concerned with the tidal movement of air in and out of the lungs. For speech production, mechanical ventilation will be the primary focus.

To produce sound, an energy source is needed to initiate the process. For speech, this energy source is the respiratory system, causing air pressure variations that result in airflow out of the respiratory tract and into the vocal tract. During inhalation, the diaphragm contracts and lowers allowing the thoracic cavity to expand and the lungs to fill with air. This causes a low pressure gradient, allowing the air to rush into the lungs. The pressure then equalizes as air is sustained in the lungs. Exhalation is the more passive mechanism of the inhalation/exhalation process. Exhalation causes relaxation of the diaphragm causing it to return to its normal position and shape. This in turn causes increased pressure gradient compared to outside the lungs, which ultimately results in air flow out of the lung cavity. The entire process of breathing (inspiration and expiration) is known as one respiratory cycle. At rest, this takes place 12 to 15 times a minute. Speech production occurs upon exhalation. During speech production, the time for inhalation is often reduced while the exhalation time is increased.

### Phonation

The phonatory process, or voicing, occurs when air is expelled from the lungs through the glottis (space between the vocal folds). As air passes through this area, a lower pressure gradient occurs within the larynx. When this drop becomes sufficiently large, the vocal folds begin oscillating. This oscillation causes vibration, which is often referred to as the engine of the voicing mechanism. Vocal fold motion occurs in a wavelike fashion with lateral undulations as well as superior and inferior movements. The oscillation of the vocal folds serves to modulate the pressure and flow of the air through the larynx. This airflow is modulated and is the main source of voiced sounds. A normal voice is best described as the product of a controlled exhalation of air, steady maintenance of subglottic air pressures, and delicately balanced vocal folds movement. Any

perturbation to this complex process can result in a perceived vocal impairment.

### Resonation

The raw vocal tone is modified and amplified by resonance within the pharyngeal, oral, and nasal cavities, which are referred to collectively as the vocal tract. The innumerable configurations of the shape of the vocal tract provide the human voice with a tremendous range of variation in perceived quality.

Following transit through the larynx, the air is modulated by (a) changing the tension of the pharyngeal walls; (b) raising or depressing the larynx; (c) modifying the position of the jaw, tongue, and lips; and (d) occluding or lowering the soft palate. Valving of the velopharyngeal region requires the closure of the nasal cavity from the oral cavity for production of all sounds other than the /m/, /n/, and /ng/ sounds. This valving is achieved in a three-dimensional pattern of closure typically described as retraction and elevation of the soft palate/velum, anterior movement of the posterior pharyngeal wall, and inward movement of the lateral pharyngeal walls. Various patterns of velopharyngeal closure were initially described by Skolnick in 1973 and adopted by others to better understand the closure mechanism (2,3).

### Articulation

The final production of sound occurs as air is expelled through and manipulated within the oral cavity by the movements of the lips, teeth, and tongue. Coordinated actions of the tongue, lips, jaw, and soft palate regulate the air stream and produce the meaningful sounds of speech called phonemes. These structures, often referred to as articulators, relax, compress, or momentarily stop the air stream in varied ways to produce specific vowels or consonants. The addition or elimination of a voicing component from the larynx, during sound production, dictates whether a consonant is voiced or voiceless.

### Neural Control

Motor control for respiration, phonation, resonance, and articulation requires complex neural networking, regulation, and monitoring of muscle activity of both the central nervous system and the peripheral nervous system. Many of the speech systems and musculature used for speech production are also used for oropharyngeal swallowing and mastication. It is natural that a large amount of overlap exists in the neural networking, although affecting different behaviors. The central nervous system and peripheral nervous system are the primary controls for the neural networking, though the extrapyramidal nervous system also plays a role. Although studied since the 17th century, many questions remain in determining the brain regions involved in speech production. Neuroimaging advances continue to attempt to solve this dilemma; however, inconsistencies in normal subject's activation patterns continue to be found (4). Speech involves simultaneous activity in various regions of the brain that are largely spread over the cortical and subcortical areas. Additionally, clinical data of patients with cerebellar lesions or Parkinson's disease suggest that the cerebellum and the brainstem are engaged in the motor control of speech (5–7).

## MOTOR SPEECH DISORDERS

### Dysarthria

The dysarthrias are a group of motor speech disorders characterized by slow, weak, imprecise, or uncoordinated movements of speech musculature. Rather than a single neurological disorder, the dysarthrias vary along a number of different dimensions. As stated above, the neuroanatomical site of a lesion causing dysarthria can be one or a combination of the cerebrum, cerebellum, brainstem, and cranial nerves. The prevalence and incidence of dysarthria are not precisely known. Dysarthria can be a symptom of a neurological disease process with a constellation of other symptoms, or it can stand alone with a disease. Approximately one third of individuals with traumatic brain injury (TBI) may be dysarthric with nearly double that prevalence during the acute phase of recovery (8,9). Dysarthria is frequently seen in 50% to 90% of parkinsonian patients with the increased prevalence as the disease progresses (10). Additionally, dysarthria is often a preliminary sign of amyotrophic lateral sclerosis or can become present as the disease progresses. In larger tertiary care medical centers, dysarthria was the primary communication impairment with acquired neurological disease seen for speech-language pathology evaluations over a 4-year period (11).

The dysarthrias can be classified by time of onset, site of lesion, and etiology; however, the most widely used classification was first described by Darley et al. (12–14). This is often referred to as the Mayo Clinic Classification System with each type representing a perceived and distinguishable

grouping of speech characteristics with a presumed underlying pathophysiology or locus of lesion.

As a first step, differential diagnosis involves distinguishing the dysarthrias from other neurogenic communication disorders. The dysarthrias are distinct from aphasia in that language function (i.e., word retrieval, comprehension of both verbal and written language) is preserved in dysarthria but impaired in aphasia. Although both apraxia and dysarthria are considered motor speech disorders, they can be distinguished on the basis of several clinical features. In apraxia, automatic (i.e., nonspeech) movements are intact, whereas in most dysarthrias, they are not. Highly consistent articulatory errors are characteristic of dysarthria, whereas inconsistent errors are a hallmark of apraxia. Finally, in most dysarthrias, all speech systems, including respiration, phonation, resonance, and articulation, are involved; whereas in apraxia, respiratory or phonatory involvement is rare. It should be recognized that patients often can have elements of both dysarthria and apraxia, particularly those with bilateral brain damage.

Differential diagnosis among the dysarthrias seems to have received more systematic attention than any other aspect of the disorder. Table 15-1 summarizes information related to the various dysarthrias (15). In studies conducted at the Mayo Clinic, the perceptual features of the speech of seven groups of dysarthric patients were examined (12,13). These groups consisted of patients who were unequivocally diagnosed as having one of the following conditions: pseudobulbar palsy, bulbar palsy, amyotrophic lateral sclerosis, cerebellar lesions, parkinsonism,

**TABLE 15.1** Summary of the Etiologies, Neuropathologies, and Neuromuscular Deficits Characteristic of the Common Dysarthrias

Type	Example	Location of Neuropathology	Neuromuscular Deficit
Flaccid	Bulbar palsy	Lower motor neuron	Muscular weakness; hypotonia
Spastic	Pseudobulbar palsy	Bilateral upper motor neuron	Reduced range, force, speed; hypertonia
Ataxic	Cerebellar ataxia	Cerebellum (or tracts)	Hypotonia; reduced speed; inaccurate range, timing, direction
Hypokinetic	Parkinsonism	Extrapyramidal system	Markedly reduced range; variable speed of repetitive movements; movement arresting rigidity
Hyperkinetic			
Quick	Chorea Myoclonus Gilles de la Tourette's syndrome	Extrapyramidal system	Quick, unsustained, random, involuntary movements
Slow	Athetosis Dyskinesias Dystonia	Extrapyramidal system	Sustained, distorted movements and postures; slowness; variable Hypertonus
Tremors	Organic voice tremor	Extrapyramidal system	Involuntary, rhythmic, purposeless, oscillatory movements
Mixed	Amyotrophic lateral sclerosis Multiple sclerosis Wilson's disease	Multiple motor systems	Muscular weakness, limited range and speed

dystonia, and choreoathetosis. Speech samples were rated along 38 dimensions that described pitch characteristics, loudness, vocal quality, respiration, prosody, articulation, and general impression. Results of these studies indicated that each of the seven neurological disorders could be characterized by a unique set of clusters of deviant speech dimensions and that no two disorders had the same set of clusters. Thus, differential diagnosis among the dysarthrias can be made, in part, on the basis that one type of dysarthria sounds different from the others. However, single features such as imprecise consonant production or nasal emission may not be sufficient to distinguish one type of dysarthria from another. Instead, differential diagnosis is made on the basis of clusters of features reflecting underlying pathophysiology and the findings on examination of the musculature. The following summarizes the major types of dysarthrias, their primary distinguishing perceptual attribute, and their presumed underlying localization and distinguishable deficit.

### **Flaccid Dysarthria**

Flaccid dysarthria is due to weakness in cranial or spinal column nerve innervations to the speech systems. Its specific characteristics depend on which nerve is involved. Nerves affecting articulation include trigeminal, facial, or hypoglossal. The vagus nerve contributes to voice and resonatory dysarthria primarily seen with breathy, hoarse, and diplophonic speech. Spinal respiratory nerves can also be affected with deficits in breath patterning for speech, often causing production of short phrases. Most common speech characteristics include hypernasality, breathiness, diplophonia, nasal emission, audible inspiration (stridor), short phrases, and rapid deterioration and recovery with rest. Brainstem stroke or brain injury is a common cause of flaccid dysarthria (14).

### **Spastic Dysarthria**

Spastic dysarthria is usually associated with bilateral lesions of upper motor neuron pathways that innervate the relevant cranial nerve and spinal nerve. Its distinguishable characteristics are attributed to spasticity, and they often include a harsh, strained vocal quality, slow speech rate, pitch breaks, and variable loudness. All speech systems are typically affected with this classification (14).

### **Ataxic Dysarthria**
